The International Continence Society (ICS) defines **nocturia as voiding that occurs during the hours of sleep (i.e., voiding that is preceded and not necessarily followed by sleep)** (Hashim et al., 2017; van Kerrebroeck et al., 2002). Key terms are listed in Table 119.1. Some clinicians do not consider one void during the night to be clinically significant. This may be because several studies have shown that less than two voids per night does not generate bother and that two or more voids per night can impair quality of life (Häkkinen et al., 2006; Hernández et al., 2008; Tikkinen et al., 2009b). **The definition of nocturia does not take into account the patient's degree of bother.** For example, one patient who voids once per night may report being very bothered versus another patient who voids two or three times per night who may report little bother. **Degree of bother influences quality of life.** According to the Boston Area Community Health (BACH) Survey, a population-based study of 5502 men and women 30 to 79 years of age, nocturia is associated with a decreased quality of life and an increased prevalence of depressive symptoms in both men and women (Kupelian et al., 2012). Compared with those with low bother, patients reporting high levels of nocturia-specific bother were found to be significantly more likely to have difficulty initiating sleep (47.7 minutes ± 34.4 vs. 23.5 minutes ± 13.6, *P* = .05), difficulty returning to sleep (28.9 minutes ± 16.1 vs. 15.4 minutes ± 9.6, *P* = .03), and greater morning fatigue (3.3 ± 0.7 vs. 2.5 ± 1.0, *P* = .04). The subjective morning fatigue and sleep ratings scale ranges from 1 to 7; higher scores equate to worse fatigue or sleep characteristics (Vaughan et al., 2012). In a prospective study of various sleep parameters and nocturia in a cohort of community-dwelling men and women, nocturia, common among older individuals with insomnia, was associated with both increased subjective nocturnal and decreased daytime wakefulness (Zeitzer et al., 2013).

TABLE 119.1

Key Terms and Definitions

TERM	DEFINITION
Night	The period between going to bed with the intention of sleeping and waking with the intention of arising
Nocturia	Waking one or more times to void during the hours of sleep; each void is preceded and followed by sleep
Total urine volume (TUV)	Total volume of urine produced during a 24-hour period
First-morning void	The first void after waking with the intention of rising
Nocturnal urine volume (NUV)	Total volume of urine passed during the night, including the first-morning void
Maximum voided volume (MVV)	The largest single voided volume in a 24-hr period
Nighttime frequency or actual number of nightly voids (ANV)	The number of voids recorded from the time the individual goes to bed with the intention of sleeping, to the time the individual wakes with the intention of rising
Nocturia index (Ni)	Ni = NUV/MVV; when Ni > 1 NUV exceeds maximum storage capacity and nocturia or enuresis occurs
Nocturnal polyuria	Nocturnal volume >20%-33% of total 24-hr volume (age dependent), other definitions include: NUV >6.4 mL/kg NUV >0.9 mL/min (54 mL/h) NUV >1.5 mL/min (>90 mL/h)
Nocturnal polyuria index (NPi)	NPi = NUV/TUV; if NPi > 0.20-0.33 (age dependent); patient has nocturnal polyuria
Predicted number of nightly voids (PNV)	PNV = Ni − 1, used for calculation of NBCi
Nocturnal bladder capacity index (NBCi)	NBCi = ANV − PNV; NBCi > 0 indicates that nocturia will occur at voided volumes < MVV. NBCi >2 associated with severe nocturia
Global polyuria	24-hour voided volume of >2.8 L in a 70-kg adult (>40 mL/kg)
Nocturnal enuresis	Voiding occurring during sleep

Modified from van Kerrebroeck P. Standardization of terminology in nocturia: commentary on the ICS report. *BJU Int* 90(Suppl 3):16–17, 2002.

Nocturia Is Common

Nocturia affects people of different ages, races, and genders all over the world. The BACH Survey, composed of 5502 men and women between 30 and 79 years of age, found that the overall **prevalence of nocturia (more than one void per night) was 28.4%, 25.2% among men and 31.3% among women** (Fitzgerald et al., 2007). A review of 43 pertinent articles revealed that prevalence rates of nocturia in younger men (20 to 40 years of age) were one or more voids in 11% to 35% and two or more voids in 2% to 17%. In older men (>70 years), rates were one or more voids in 69% to 93% and two or more voids in 29% to 59%. Prevalence rates in younger women were one or more voids in 20% to 44% and two or more voids in 4% to 18%. In older women, rates were one or more voids in 74% to 77% and two or more voids in 28% to 62%. It is noteworthy that **one in every five or six people 20 to 40 years of age wakes two or more times per night and that up to nearly three in every five people older than 70 years of age wake to void two or more times nightly** (Bosch and Weiss, 2010). The Fujiwara-Kyo study included 4427 men and women older than 65 years of age. Nocturia was defined as awakening to void two or more times per night. In this population, the prevalence was reported to be 47% at baseline and 50% 1 year later. The incidence was found to be 20%, and the remission rate was 15%. The authors showed that women and younger patients were more likely to spontaneously remit (Hirayama et al., 2013).

The prevalence of nocturia in both men and women increases with age (Bosch and Weiss, 2010). In a survey of 1424 elderly individuals (55 to 84 years of age), 53% of the sample listed nocturia as a self-perceived cause of nocturnal sleep disturbance every night or almost every night (Bliwise et al., 2009). Data acquisition methodology regarding nocturia may influence calculated prevalence. In the Krimpen study, a Dutch cohort of community-dwelling men 50 to 78 years of age, the International Prostate Symptom Score (IPSS) nocturia question overestimated the percentage, with nocturia three times or more compared with recordings on frequency-volume charts, in younger men (<60 years). In contrast, older men (>60 years) underestimated their nighttime frequency when scoring the IPSS nocturia question. In the Krimpen study, nocturia was three times more prevalent in men with low functional bladder capacity (<300 mL) than in men with greater capacity (Bosch and van Doorn, 2012).

Association of Nocturia With Early Mortality

Nocturia affects both quality and quantity of life. Several studies have implicated nocturia in overall survival. In the Third National Health and Nutrition Examination Survey (NHANES III), a US population-based sample of 7455 men and 8533 women, two or more voids per night were associated with poorer survival compared with zero to one voids per night. This was particularly true in subjects younger than 65 years of age (Kupelian et al., 2011). In a community sample of 784 Japanese individuals 70 years of age and older, subjects with nocturia were at greater risk for skeletal fracture and death than those without nocturia during the 5-year observation period, even when adjusting for covariates including diabetes; smoking status; history of coronary disease, renal disease, and stroke; and use of tranquilizers, hypnotics, and diuretics (Nakagawa et al., 2010). In contrast, the Krimpen study, which analyzed 1114 men 50 to 78 years of age based on frequency-volume chart data, determined that the association between nocturia and mortality was explained by confounding factors including age, chronic obstructive pulmonary disease, smoking, and hypertension (age being the most profound). Specifically, nocturia was associated with increased mortality in the univariate analysis but was not associated with mortality in the multivariate analysis (van Doorn et al., 2012).

Nocturia affects sleep efficiency and sleep latency. Sleep efficiency is defined as actual time asleep (minutes) divided by total time of intended sleep (minutes); normal is considered greater than 85%. Sleep latency is defined as the time it takes to go from being completely awake to being completely asleep. Dew et al. (2003) showed that older adults with certain electroencephalography (EEG) sleep characteristics have an increased risk for dying independent of age, gender, and medical comorbidities. Individuals with sleep latency times of greater than 30 minutes were found to have greater than twice the risk for death, and those with sleep efficiency less than 80% were found to have nearly twice the risk for death when controlling for age, gender, and medical burden. Vaughan et al. (2013) prospectively analyzed 63 patients with Parkinson's disease using the IPSS and polysomnography. Of the 60 who completed the IPSS, 37 (61%) reported two or more episodes of nocturia. These patients demonstrated lower polysomnography-defined sleep efficiency and whole-night total sleep time than patients with zero to one episode of nocturia per night. Also, patients who reported two or three episodes of nocturia with *high* bother on the IPSS demonstrated lower whole-night total sleep time (281 ± 116 minutes vs. 373 ± 59 minutes, $P = .03$) and poorer sleep efficiency (59% ± 23% vs. 76% ± 11%, $P = .04$) compared with participants who reported two or three episodes of nocturia with *low* bother. These results show that individuals with higher bother on the IPSS experience poorer sleep as defined by polysomnography and that patients with Parkinson's disease and nocturia have poor sleep in general. Bliwise et al. (2015) demonstrated that a shorter first uninterrupted sleep period (FUSP) is associated with lower sleep quality, shorter sleep duration, poorer sleep efficiency, and greater daytime dysfunction. In a subsequent study, the authors concluded that simple interventions to increase FUSP results in better sleep quality (Tyagi et al., 2017). Increases in FUSP have been shown to improve the PSQI (Pittsburgh Sleep Quality Index) or overall sleep quality as suggested by Bliwise et al. (2014). Better sleep quality, measured by increases in FUSP, may also help reduce blood glucose levels and improve overall cardiometabolic health (Juul et al., 2016).

It is not surprising that nocturia is associated with an increased risk for mortality, because **nocturia can be a symptom of serious systemic illnesses including hypertension, diabetes, heart disease, and kidney disease** (Ancoli-Israel et al., 2012). Bliwise et al. (2017) showed that both men and women in a racially diverse population have elevated glucose levels in individuals habitually obtaining less than 7 hours of sleep. Sleep loss can negatively affect health by decreasing immune function, increasing the risk for cardiovascular disease, and increasing the risk for developing obesity and type 2 diabetes (Asplund, 2005; Spiegel et al., 2004). This can be better understood by defining the various states and stages of sleep. **Sleep is divided into two states: rapid eye movement (REM) and non–rapid eye movement (NREM).** NREM accounts for approximately 75% of total sleep time and is divided into four stages. Stage 1 accounts for the transition from wakefulness to sleep; stage 2 accounts for light sleep; and stages 3 and 4 consist of deep, restorative sleep or slow-wave sleep (SWS) (Keenan, 1999). The normal sleep cycle alternates between stages 1 and 4 of NREM and REM sleep (Roehrs, 2000). Each night consists of roughly four to six sleep cycles. In the beginning of the night, SWS predominates, whereas in the later hours of the night REM sleep predominates. Awakening during REM sleep is more natural and may still leave one feeling rested compared with awakening during SWS, which leaves one to experience daytime fatigue and discomfort irrespective of the total length of sleep time (Lentz et al., 1999). Because the first nocturia episode often occurs within the first 2 to 3 hours of sleep on average, SWS may be interrupted by nocturia, which may explain why nocturics often experience decreased quality of life (van Kerrebroeck et al., 2007).

SWS plays a role in glucose homeostasis. Tasali et al. (2008) demonstrated that suppression of SWS for three nights impairs glucose tolerance and insulin sensitivity. This explains why aging individuals with impaired SWS are at higher risk for developing type 2 diabetes. The body's regulation of SWS is a homeostatic process as well. This was illustrated by a study that monitored the EEG activity of both control subjects and subjects receiving acoustic stimulation during the first 3 hours of sleep to decrease the amount of SWS. Individuals who had decreased SWS early in the night because of acoustic stimulation were noted to have inadequately compensated amounts of SWS later in the night (Dijk, 2009). In a related study, when the first void occurred during the first two sleep cycles, patients had (on average) 37 minutes of SWS compared with those in whom the first void occurred after the first two sleep cycles, tallying (on average) 56 minutes of SWS (P = .023). The actual number of nightly voids (ANV) also affected SWS. Patients who experienced zero to one void per night had an average of 62 minutes of SWS compared with those who experienced two or more voids per night, who had an average of 40 minutes of SWS (P = .014) (Torimoto et al., 2013). In the Sleep Heart Health Study, 2813 men and 3097 women between 40 and 100 years of age were enrolled in a community-based prospective study that examined the cardiovascular consequences of sleep-disordered breathing. Usual sleep durations were obtained by questionnaire, and hypertension was defined as systolic blood pressure (BP) greater than 104 mm Hg, diastolic BP greater than 90 mm Hg, or the use of medication to treat hypertension. Usual sleep duration above or below the median of 7 to 8 hours per night was associated with an increased risk for hypertension, particularly in individuals who sleep less than 6 hours per night (Gottlieb et al., 2006). **Sleep duration less than 6 hours or greater than 8 hours may be a factor predisposing to metabolic syndrome. Compared with those sleeping 7 to 8 hours per night, those sleeping for longer or shorter durations were at least 45% more likely to have metabolic syndrome** (Hall et al., 2008). A recent analysis of the BACH survey revealed that among baseline lower urinary tract symptoms (LUTS), only nocturia was associated with incident sleep problems at 5-year follow-up (odds ratio [OR] 1.98 with or without body mass index adjustment, $P < .001$) (Araujo et al., 2014). In a US cohort of 2447 men (40 to 79 years of age) who were followed for a median of 17 years, nocturia was found to be a marker for coronary heart disease in men younger than 60 years of age (adjusted OR 1.36) and a marker for death in men 60 years of age and older (OR 1.48) (Lightner et al., 2012). A systematic review and meta-analysis found consistent evidence of increased mortality for men or women with nocturia equivalent to a 28% excess risk per year (Pesonen et al., 2014). **In summation, present evidence points to nocturia as a risk factor for future development of both metabolic syndrome and early mortality as a result of its proxy**

effect on sleep impairment.

Nocturia is among the LUTS most strongly associated with falls (Parsons et al., 2009) and is a risk factor for hip fractures (regardless of age). In an Austrian study, 1820 men 40 to 80 years of age completed the IPSS. Although the IPSS was not correlated with the occurrence of hip fractures, nocturia (two or more voids per night) was an age-independent risk factor for hip fracture (OR 1.36; 95% confidence interval [CI] 1.03, 1.80; *P* = .03) (Temml et al., 2009). Hip fracture has been associated with an in-hospital mortality rate of 5.3%, hence providing explanation for early mortality related to nocturia (Alvarez-Nebreda et al., 2008). What is not clear is whether successful therapy for nocturia could diminish falls, fractures, metabolic syndrome, or early mortality.

Costs to Society

Assuming that 28 million people 25 years of age or older in the United States experience nocturia (more than two voids per night) and this results in a productivity loss of 127 hours per individual, then based on the average US wage of $17.38 per hour (based on small-size, private industry salaries), the economic value of productivity lost in 2008 was $61 billion (Holm-Larsen et al., 2010). In a Swedish study, productivity, vitality, and quality of life were assessed in more than 200 professionally active adults with one or more voids per night. Compared with controls, patients with nocturia had significantly increased work impairment (assessed using a work productivity and activity impairment questionnaire) and increased impairment in nonwork activities (*P* < .001). Patients with nocturia also had significantly reduced vitality (based on responses to Short Form-36 Health Survey) and reduced overall quality of life (based on responses to the EQ-5D) compared with controls (*P* < .001). EQ-5D is a standardized instrument for assessing health status. It also was found that work impairment increased and vitality decreased in proportion to nocturia severity (*P* < .05, < .01, respectively) (Kobelt et al., 2003). Nocturnal awakenings were found to be associated with sleepiness, naps, and sick leave in the general adult population in a study in which 76% of respondents reported needing to void as the reason for awakening (i.e., true nocturia) (Ohayon, 2008).

Key Points: Rationale for Evaluation and Management

- Nocturia is waking during intended sleep because of the desire to void.
- Two or more voids per night appears to be clinically significant.
- The prevalence of nocturia increases with age.
- Nocturia is costly to society because it can lead to decreased productivity, increased time away from work, and increased falls and fractures.
- Nocturia impairs sleep efficiency, sleep latency, and SWS, and is associated with increased mortality.
- Nocturia can be a symptom of serious systemic illness, including hypertension, diabetes, heart disease, and kidney disease, leading to metabolic syndrome.

Evaluation

The cause of nocturia can be multifactorial and complex; therefore, the evaluation of nocturia should be focused and systematic, beginning with a complete history and physical examination. By way of example, a history of medication use, such as lithium, should alert the clinician to the possibility of global polyuria as a result of drug-induced nephrogenic diabetes insipidus. Physical findings pertinent to an evaluation of nocturia might include peripheral edema resulting from cardiac disease, nephrotic syndrome, or venous insufficiency and be associated with nocturnal polyuria. Physical findings such as obesity and short neck might be suggestive of obstructive sleep apnea (OSA); the latter also is associated with nocturnal polyuria. In the population-based Finnish National Nocturia and Overactive Bladder (FINNO) study, numerous risk factors for nocturia were identified, such as urinary urgency, benign prostatic hyperplasia (BPH), snoring, obesity, antidepressant usage, restless legs syndrome, and prostate cancer in men, and obesity, urinary urgency, snoring, diabetes, restless legs syndrome, and coronary artery disease in women. However, none of the identified risk factors were associated with nocturia in more than 50% of the affected subjects of both sexes, highlighting the multifactorial cause of nocturia (Tikkinen et al., 2009a). Hence, it is essential that clinicians consider factors beyond the LUT when treating bothersome nocturia.

Some of the questions to consider when evaluating nocturia are: How is nighttime defined? Is the patient awakened by the need to void, or does the patient void because he or she is already awake? A recent study by Weinberger et al. (2013) showed that 92% of men and 90% of women are awakened by the urge to void, leaving the remainder as incidental nocturnal convenience voids. **Nighttime is defined as the period between going to bed with the intention of sleeping and awakening with the intention of arising** (van Kerrebroeck et al., 2002). This definition becomes relevant when explaining to the patient how to complete a 24-hour voiding diary or **frequency-volume chart,** the most valuable objective instrument in evaluating nocturia. When completing a frequency-volume chart, the patient must be aware that nocturnal voids are preceded and followed by the intention of sleep regardless of time of day. Because at least 16% of the US population consists of shift workers who occasionally sleep during the day, it is important to remember that nocturia may occur during the day (Beers, 2000). Changing time zones (jet lag) also complicates the definition of nighttime. Before having a patient complete a frequency-volume chart, it is best to allow sufficient recovery time to eliminate the effect of jet lag.

Although the first-morning void after a night's sleep is counted toward daytime (diurnal) frequency rather than the ANV, the volume of the first-morning void is included in the tally of nocturnal voided volume. Hence, **nocturnal urine volume (NUV)** is the sum of all nocturnally voided volumes plus that of the first-morning void, because the urine in the latter void is produced during the hours of sleep. An untested assumption is that most patients void before bedtime. Hence the first nocturia-related void is also assumed to have been excreted during the hours of sleep. **Maximum voided volume (MVV)** is the largest voided volume of urine during a 24-hour period. The nocturia index (Ni) is calculated by dividing NUV by MVV (Weiss et al., 1999). When NUV is greater than MVV, the Ni is greater than 1, in which case nocturia must occur if the patient awakens, and, if not, enuresis will occur. Epstein et al. showed that improvements in nocturia were associated with a decrease in 24-hour urine volume and NUV, but not MVV, suggesting that improved patients consumed less fluid (Epstein et al., 2018). Improved patients also had an increase in FUSP, suggesting that therapy for nocturia can improve sleep architecture.

Nocturnal polyuria is increased production of urine at night that is offset by lowered daytime urine production, such that 24-hour urine volume remains within normal limits (Asplund, 1995). Because urine is normally produced in an age-dependent circadian pattern, it is worthwhile to determine the nocturnal polyuria index (NPi), which is the percentage of urine produced during nighttime (calculated as NUV/total 24-hour urine volume). In healthy adults 21 to 35 years of age, the mean NPi = 0.14 versus those 65 years of age and older, whose mean NPi = 0.34 (Rembratt et al., 2002). The NPi for middle-aged adults lies between 0.14 and 0.34. Accordingly, to simplify the definition, the ICS has defined NP as NPi greater than 20% (0.20) in young adults and greater than 33% (0.33) in patients older than 65 years of age when 24-hour urine production is within normal limits (van Kerrebroeck et al., 2002). Other definitions of nocturnal polyuria include NUV greater than 6.4 mL/kg and NUV greater than 0.9 mL/min (54 mL/h) (Matthiesen et al., 1996). Blanker et al. (2002) defined nocturnal polyuria as greater than 1.5 mL/min (>90 mL/h), which was 2 standard deviations above the mean of 60 mL/h in their study of men 50 to 78 years of age. van Doorn et al. (2013) found that prevalence, incidence, and resolution rates of nocturnal polyuria vary greatly depending on which definition is used. When analyzing the cohort of 1688 men 50 to 78 years of age in the Krimpen study, men who had nocturnal polyuria, defined as nocturnal urine production greater than 90 mL/h (NUP90), had a baseline prevalence of 15.0% that increased to 21.7% after 6.5 years. When nocturnal polyuria was defined as NUV greater than 33% of 24-hour voided volume (NUV33), baseline prevalence was 77.8% and increased to 80.5% after 6.5 years. At baseline, NUV33 was prevalent in 91.9% of men with nocturia and 70.1% of men without nocturia, and NUP90 was prevalent in 27.7% of men with nocturia and 8.0% of those without nocturia (van Doorn et al., 2013). A universally accepted definition of nocturnal polyuria has yet to be defined.

Everaert et al. (2018) recently studied the relationship between diuresis rate and urge perception score. Their goal was to see if diuresis rate has an effect on daytime and nighttime urinary urgency and frequency by analyzing 202 diaries from 126 unique patients (110 men, 16 women, mean age = 65). They found that nocturnal diuresis rate did correlate with nocturia severity (ANV), but there was no correlation between diuresis rate and urge perception score. This supports that nocturnal urgency is multifactorial and complex.

Another cause of nocturia is **decreased bladder capacity.** This can result from either a global decrease in bladder capacity as expressed by a low MVV or simply a decrease in nocturnal bladder capacity. In both instances, NUV exceeds nocturnal bladder capacity, and the patient arises because of the need to void. The **nocturnal bladder capacity index (NBCi)** is a useful means to examine the relationship between the patient's own bladder capacity and nocturnal voided volumes during a 24-hour period. NBCi is calculated by subtracting the predicted number of nightly voids (PNV) from the ANV. The PNV is calculated by subtracting 1 from Ni (NUV/MVV). Therefore NBCi = (ANV − PNV), where PNV = (Ni − 1). If NBCi is greater than 0, then nocturia occurs at volumes less than MVV (Weiss, 2012). As an example, a patient who voids eight times per night (ANV = 8), voids a total of 800 mL during the intended hours of sleep (NUV = 800 mL), and has an MVV of 200 mL would have an Ni of 4 (Ni = NUV/MVV = 800 mL/200 mL = 4). This patient's PNV = Ni − 1 = 4 − 1 = 3. Therefore, this patient's NBCi = ANV − PNV = 8 − 3 = 5. An NBCi of 5 indicates a substantially diminished nocturnal bladder capacity. Although there is a significant association between patients with severe nocturia and NBCi greater than 2 (Weiss et al, 1999), an analysis of a sample of normal volunteers suggested that nocturia is related to diminished nocturnal bladder capacity when

NBCi is greater than 1.3 (Burton et al, 2011).

Global polyuria also can cause an individual to awaken to void during the hours of sleep. Global polyuria is defined as 24-hour urine output greater than 40 mL/kg causing both daytime urinary frequency and nocturia (Oelke and van Kerrebroeck, 2012). For example, a 75-kg patient would be considered to have global polyuria if the 24-hour urine output exceeded 3000 mL (75 kg × 40 mL/kg = 3000 mL). It is worthwhile to note that nocturia can have a mixed cause, as well; that is, a patient may awaken to void during the hours of sleep because of diminished nocturnal bladder capacity combined with either or both nocturnal polyuria or global polyuria. In an effort to increase patient compliance, a nocturnal FVC combined with 24-hour urine volume (omitting capture of detailed daytime voided volumes) may substitute for a standard FVC (Denys et al., 2016).

Key Points: Evaluation

- Evaluation of nocturia should include a relevant history and physical examination.
- A frequency-volume chart or a voiding diary is the single most useful tool in evaluating and classifying the cause of nocturia.
- When NUV is greater than MVV, the Ni is greater than 1, and nocturia will occur if the patient awakens. If the patient does not awaken, enuresis will occur.
- Nocturnal polyuria is increased production of urine at night and has several definitions.
- Global polyuria is defined as 24-hour urine output in excess of 40 mL/kg, causing both daytime urinary frequency and nocturia.

Cause and Management

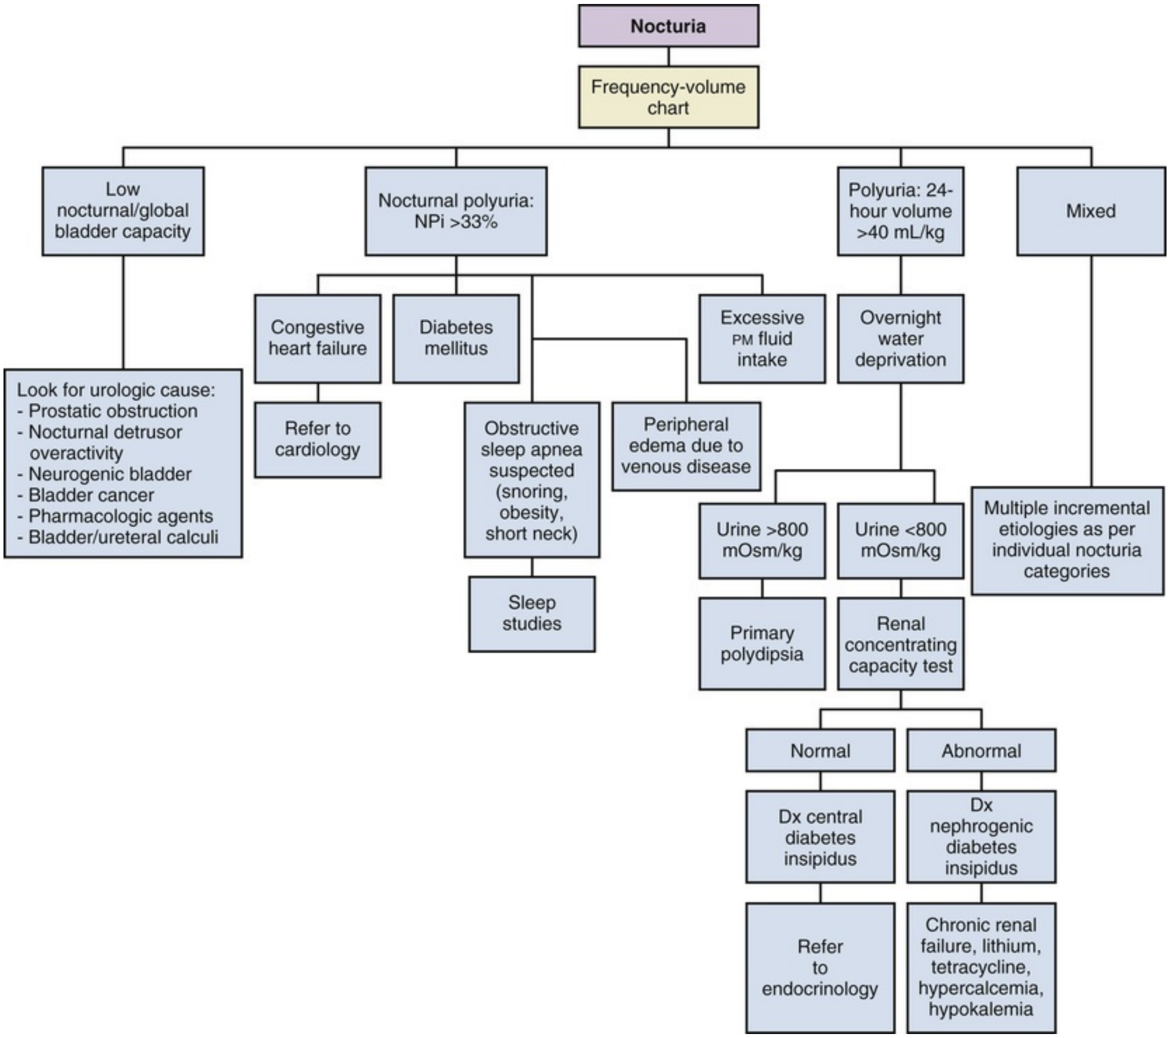
Classification of nocturia using a frequency-volume chart, along with a focused history and physical examination, unlocks up to 17 different underlying medical conditions that may potentially contribute to its genesis (Table 119.2). Diary-based classification of nocturia also can help the urologist follow a treatment algorithm (Fig. 119.1). Although unproved, it is assumed that more accurate classification leads to better treatment outcomes.

TABLE 119.2

Diary-Based Classification of Nocturia and Respective Underlying Medical Conditions

NOCTURIA CATEGORY	UNDERLYING MEDICAL CONDITIONS
Nocturnal polyuria	Excessive nighttime fluid intake Peripheral edema Obstructive sleep apnea Diabetes mellitus Congestive heart failure
Diminished global or low nocturnal bladder capacity	Ureteral calculi Bladder calculi Pharmacologic agents Anxiety disorders Learned voiding dysfunction Cancer of bladder, prostate, or urethra Neurogenic bladder Nocturnal detrusor overactivity Prostatic obstruction
Global (24-hour) polyuria	Primary polydipsia Diabetes insipidus Diabetes mellitus

Modified from Weiss JP. Assessment of nocturia and nocturnal polyuria. In: Oelke M, van Kerrebroeck P, eds. *Current aspects on diagnosis and treatment of nocturia*. London, 2012, UNI MED Verlag AG, p 72.



Nocturia
Frequency-volume chart
Low nocturnal/global bladder capacity
Nocturnal polyuria: NPi >33%
Polyuria: 24-hour volume >40 mL/kg
Mixed
Look for urologic cause:
- Prostatic obstruction
- Nocturnal detrusor overactivity
- Neurogenic bladder
- Bladder cancer
- Pharmacologic agents
- Bladder/ureteral calculi
Congestive heart failure
Diabetes mellitus
Excessive PM fluid intake
Overnight water deprivation
Refer to cardiology
Obstructive sleep apnea suspected (snoring, obesity, short neck)
Peripheral edema due to venous disease
Sleep studies
Urine >800 mOsm/kg
Urine <800 mOsm/kg
Multiple incremental etiologies as per individual nocturia categories
Primary polydipsia
Renal concentrating capacity test
Normal
Abnormal
Dx central diabetes insipidus
Dx nephrogenic diabetes insipidus
Refer to endocrinology
Chronic renal failure, lithium, tetracycline, hypercalcemia, hypokalemia

FIG. 119.1 Flowchart depicting comprehensive evaluation of nocturia and algorithm for treatment. *Dx,* Diagnosis; *NPi,* nocturnal polyuria index. (Modified from Weiss JP. Assessment of nocturia and nocturnal polyuria. In: Oelke M, van Kerrebroeck P, eds. *Current aspects on diagnosis and treatment of nocturia.* London, 2012, UNI MED Verlag AG, p 73.)

Nocturnal Polyuria

Epidemiology and Causes

The definition of nocturnal polyuria has a major impact on its perceived prevalence. Among patients with nocturia, nocturnal polyuria seems to be quite common. In a population recruited for a pharmacologic study of nocturia, 819 (88%) of 934 subjects with nocturia (more than two voids per night) who completed a voiding diary had nocturnal polyuria (NUV >33% of 24-hour volume) (Weiss, 2009). On the other hand, in analyzing the Krimpen database, Blanker et al. (2000) found that nocturnal polyuria prevalence for men 50 to 54 and 65 to 69 years of age was 44% and 54%, respectively, at baseline and increased to 51% and 65%, respectively, after 6.5 years of follow-up when nocturnal polyuria was defined as NUV/24-hour urine volume greater than 33%. When the nocturnal polyuria definition was changed to NUV >90 mL/h, the prevalence for men 50 to 54 and 65 to 69 years of age was 14% and 23%, respectively, and increased to 19% and 26%, respectively, after 6.5 years of follow-up. In an effort to prevent the overestimation of nocturnal polyuria prevalence, van Haarst and Bosch proposed that nocturnal polyuria exists when the NPi exceeds 53% (van Haarst and Bosch, 2012).

The physiology of renal water handling is relevant to an understanding of the pathophysiology of nocturnal polyuria and its treatment. Normal circadian urine production is age dependent. In those younger than 25 years of age, NUV/total = 14%, and in those older than 65 years of age, NUV/total = 34% (Rembratt et al., 2002). Water is the largest component of the human body; the major determinant of body water is arginine vasopressin (AVP)-regulated water excretion by the kidneys. AVP is stimulated by high serum osmolality, hypovolemia, and angiotensin II, and is inhibited by natriuretic peptides and negative feedback via baroreceptors. AVP causes vasoconstriction via V_{1a} receptors and causes renal reabsorption of water through its action on V_2 receptors as follows: AVP stimulation of V_2 receptors, located in the basolateral membrane of the renal collecting tubular cell, activates a Gs subtype of guanine nucleotide-binding protein (guanosine triphosphate [GTP]), which in turn activates adenylate cyclase. The result is increased concentration of cyclic 3′-5′-adenosine monophosphate (cAMP) and activation of protein kinase A (PKA). PKA triggers vesicles containing aquaporin 2 (AQP2) to fuse with the luminal plasma membrane of the collecting tubule, thereby allowing water to enter the cell. Passive resorption of water through the basolateral membrane (aquaporins 3 and 4) along osmotic gradients by way of other water channels into the vasa recta ultimately leads to water retention (Fig. 119.2). Other factors that inhibit ADH and cause diuresis (inhibit water reabsorption) include prostaglandin E_2 (PGE_2), atrial natriuretic peptide (ANP), hypercalcemia, hypokalemia, lithium, and tetracyclines (Nielsen et al., 1999). Reversal of water diuresis, accordingly, may occur through stimulation of V_2 receptors, either by endogenous AVP or a congener thereof, such as desmopressin. Therefore, low antidiuretic hormone (ADH) levels cause a larger volume of dilute urine to be produced. During sleep hours, this translates into a greater likelihood for nocturia.

OSA is a common cause of nocturnal polyuria. OSA is defined as the sudden cessation of respiration during sleep because of airway obstruction. Older adults with severe sleep-disordered breathing have a greater number of nocturia episodes (Endeshaw et al., 2004; Yalkut et al., 1996). The mechanism behind this is as follows: Increased airway pressure leads to hypoxia, which in turn causes pulmonary vasoconstriction, the latter leading to increased right atrial transmural pressure with a resulting increase in atrial natriuretic peptide

(ANP) production and ultimately increased renal sodium and water excretion. OSA is more likely as nocturia worsens in severity; the sleep apnea incidence in men with no, one, two, and three or more episodes of nocturia is 10%, 13%, 17%, and 20%, respectively. The sleep apnea incidence in women with no, one, two, and three or more episodes of nocturia is 7%, 9%, 12%, and 19%, respectively (Hashim et al., 2011). Men and women with three or more voids per night are more likely to have severe OSA (Kaynak et al., 2004).

Management

Treating nocturnal polyuria should begin with a conservative approach. Directly address the nocturnal polyuria itself by recommending cessation of fluid intake 4 hours before bedtime, the use of compressive lower extremity stockings, and/or administration of diuretics in the mid-afternoon for edema states. Individuals who have insomnia and nocturia may benefit from behavioral therapy directed at improving the insomnia. Tyagi et al. (2014) showed that individuals with insomnia and nocturia saw a greater improvement in number of nocturnal voids when treated with behavioral therapy versus receiving printed materials (information control). The behavioral therapy group saw a decrease in total number of nocturnal voids by 6.5 ± 4.8 over a 14-day period, whereas the information control group saw an increase of nocturnal voids by 1.3 ± 1.7 ($P = .05$). In addition, treating sleep disturbances, hypertension, and obesity in patients with nocturia also may decrease the number of nightly voids and improve quality of life (Sağlam et al., 2013).

A large roster of pharmaceutical agents may contribute to nocturia (Box 119.1). Further, timing of certain medications can influence nocturnal urine output. Diuretics work by preventing water accumulation and forcing water out of the system; they are indicated in patients with lower limb venous insufficiency and congestive heart failure. Timing of diuretic administration should be during the mid-afternoon, to allow for elimination of lower extremity excess body fluid during normal waking hours. In a small randomized double-blind, placebo-controlled trial, 49 men (>50 years of age) with nocturnal polyuria were randomized to receive 40 mg of furosemide 6 hours before sleep versus placebo. Among the 43 men who completed the study, the reduction in nocturic episodes was 0.5 versus 0.0 (furosemide vs. placebo, $P = .014$). There was also a significant reduction in percentage of nighttime voided volume: −18% versus 0% (furosemide vs. placebo, $P < .001$). Therefore men with nocturnal polyuria may benefit from diuretic therapy 6 hours before sleep (Reynard et al., 1998).

Box 119.1

Drug Effects Causing Nocturia

Increased Urine Output

- Diuretics
- SSRIs (block ADH secretion)[a,b]
- Calcium channel blockers (increase ANP, block sodium reabsorption in PCT)[c]
- Tetracycline (attenuates ADH via decreases in cAMP accumulation and action)[d]
- Lithium (decreases AQP2)[e]

Insomnia and CNS Effects

- CNS stimulants
  - Dextroamphetamine
  - Methylphenidate
- Antihypertensives
  - α-Blockers
  - β-Blockers
  - Methyldopa
- Respiratory
  - Albuterol
  - Theophylline
- Decongestants
  - Phenylephrine
  - Pseudoephedrine
- Hormones (corticosteroids, thyroid)
- Psychotropics
  - MAOIs
  - SSRIs
  - Atypical antidepressants

    Dopaminergic agonists (carbidopa)
    Antiepileptics (phenytoin)

Direct Lower Urinary Tract Effects

- Ketamine
    - Direct bladder toxin
- Tiaprofenic acid (Surgam)
    - Toxic cystitis
- Cyclophosphamide

ADH, Antidiuretic hormone; *ANP,* atrial natriuretic peptide; *AQP,* aquaporin; *cAMP,* cyclic 3′5′-adenosine monophosphate; *CNS,* central nervous system; *MAOI,* monoamine oxidase inhibitor; *PCT,* proximal convoluted tubule; *SSRI,* selective serotonin reuptake inhibitor.

Imipramine is a tricyclic antidepressant with a complex pharmacologic profile, including nonsubtype-selective antimuscarinic effects, also shown to have varied effects in modulating AVP release and potentiating renal proximal tubular sodium and water reabsorption in children. (Tomasi et al., 2001).

Imipramine should be used with caution because it has been shown to prolong the PR, QRS, and QTc intervals; increase heart rate; and lower T-wave amplitude during a 4-week treatment course (Giardina et al., 1979). There have been rare reports of torsades de pointes and sudden death resulting from imipramine administration (Swanson et al., 1997).

The influence of nocturnal polyuria on nocturia therapy with antimuscarinics has been addressed in four pooled 3-month phase III randomized controlled trials, in which 2534 of 3032 patients reported nocturia at baseline (62% of these patients were classified as having nocturnal polyuria). These patients were randomized to receive solifenacin 5 mg, 10 mg, or placebo. In patients without nocturnal polyuria, there was a statistically significant reduction in nocturia: −0.18 episode reduction advantage for 5 mg versus placebo and −0.18 episode reduction advantage for 10 mg versus placebo. Nocturia episode reduction in patients with nocturnal polyuria was not significant. However, failure to achieve statistically significant decreased nocturia between drug and placebo in the nocturnal polyuria group appeared to be caused by unexpectedly high performance of placebo in the latter arm (Brubaker and Fitzgerald, 2007).

Weiss et al. (2012) defined a clinically significant improvement in nocturia as one that improves the Nocturia Quality of Life (N-QoL) score. The N-QoL questionnaire consists of 13 statements in two domains (sleep/energy and bother/concern). Patients ranked each statement from 1 (lowest QoL) to 4 (highest QoL). One fewer nocturnal void was associated with a 4.68 increase in total N-QoL score, and a 1-hour increase in the first period of undisturbed sleep was associated with a 3.68 increase in total N-QoL score. This study is interpreted as indicating that reducing nocturia improves quality of life.

Bal et al. (2012) found that nocturia mainly occurs during superficial/REM sleep and that OSA severity is directly related to both nocturia severity and daytime sleepiness, and inversely related to sleep efficiency and total sleep time. **Treatment of OSA with continuous positive airway pressure (CPAP) can improve nocturia.** In a study of 88 men with OSA, the average number of nightly voids before treatment was 3.8 ± 0.4 voids per night and after treatment with CPAP decreased to 0.7 ± 0.3 voids per night (Guilleminault et al., 2004). A significant improvement in nocturia by treating OSA with CPAP also has been observed in women (Fitzgerald et al., 2006).

Because ADH is essential in controlling urinary concentration, it is not surprising that synthetic antidiuretics have been used to treat nocturia in addition to being standard replacement therapy for polyuric conditions such as central diabetes insipidus and primary nocturnal enuresis (PNE). Desmopressin (DDAVP) is a selective V_2-receptor agonist that retains the antidiuretic properties of vasopressin but lacks its unwanted pressor activity (Vilhardt, 1990). **When bound to V_2 receptors in the renal collecting tubules, desmopressin increases water permeability, enhances water reabsorption, dilutes extracellular fluid, and concentrates urine** (Hammer and Vilhardt, 1985). There have been multiple clinical trials of nocturia patients treated with desmopressin (Table 119.3). Desmopressin currently has the following recommendations for the treatment of nocturia:

TABLE 119.3

Clinical Trials Involving Desmopressin Treatment in Patients With Nocturia

STUDY	TARGET POPULATION	MEAN AGE (RANGE)	EFFECTIVE DOSES	ROUTE OF DELIVERY	CLINICAL RESPONDERS IN TREATMENT ARM (%)
Mattiasson et al., 2002	Men	65.1 (24.2–87.6)	0.1, 0.2, 0.4 mg (dose titration)	Oral	34
Lose et al., 2003	Women	57.1 (20.6–88.7)	0.1, 0.2, 0.4 mg (dose titration)	Oral	44
Lose et al., 2004	Men and women	60.5 (21–88)	0.1, 0.2, 0.4 mg (dose titration)	Oral	67
van Kerrebroeck et al., 2007	Men and women	63.4 (19.8–94.0)	0.1, 0.2, 0.4 mg (dose titration)	Oral	33
Weiss et al., 2012	Men and women	62.0 (N/A)	100 µg (25 µg in women)	Sublingual	71
Rembratt et al., 2003	Men and women	75.5[b] (66–90)	0.2 mg	Oral	82
Kuo, 2002	Men and women	75.4 (65–84)	0.1 mg	Oral	66.7
Wang et al., 2011	Men	74.0 (65–88)	0.1 mg	Oral	61.4

Weiss et al., 2013a	Men	60.4 (N/A)	50 µg or 75 µg	Sublingual	2.04[c]

- **ICI:** Grade A (level 1 evidence) (Andersson et al., 2013)
- **European Association of Urology (EAU):** Grade A (level 1b evidence) (Gravas et al., 2016)

For maximum concentration of urine, large amounts of urea must be deposited in the interstitium of the inner renal medulla. V_2 receptor activation (e.g., by DDAVP) increases urea permeability by 400% in the terminal portions of the inner medullary collecting duct by activating an AVP-regulated urea transporter, most likely by means of PKA-induced phosphorylation (Sands, 2003). **Desmopressin tablet studies have shown long-term reduction in nocturnal voids compared with baseline in both men (48% to 58%) and women (55% to 59%)** (Lose et al., 2004) **while increasing the initial sleep period by 2 hours in both** (Lose et al., 2003; Mattiasson et al., 2002)**. Hyponatremia is a well-known undesired effect of desmopressin.** In high-dose desmopressin tablet studies, 4.9% of all patients developed hyponatremia (defined as serum sodium <130 mmol/L). Patients with hyponatremia were older, smaller, and moderately more polyuric and had slightly lower basal serum sodium level and moderately lower creatinine clearance rate than those without hyponatremia. Nearly all patients who developed hyponatremia in the tablet studies were older than 65 years of age (Rembratt et al., 2006). More recently, studies have been completed with the intraorally dispersable preparation of desmopressin (“melt”). Melt was found to decrease overall nocturia severity and to increase the 33% responder rate. In a 4-week randomized, double-blind study, 757 patients who reported three or more voids per night (90% of whom had nocturnal polyuria) received 10, 25, 50, or 100 µg of melt or placebo. Those who received placebo, 10, 25, 50, or 100 µg of melt had the following reduction in number of nocturnal voids from baseline respectively: −0.86, −0.83, −1.00, −1.18*, and −1.43* and had the following percent increase in 33% responder rate: 47%, 47%, 50%, 53%, 71%* (Weiss et al., 2012). In both men at 50 µg and women at 25 µg desmopressin melt, the odds of increasing the first uninterrupted sleep period to 4 hours or longer was significantly greater than placebo at 1 week and after months 1, 2, and 3 ($P < .0001$) (Sand et al., 2013; Weiss et al, 2013b). In a follow-up study designed to investigate the lowest possible therapeutically effective dose of desmopressin, the efficacy and safety of desmopressin orally disintegrating tablets (ODT) 50 µg and 75 µg in men with nocturia (two or more nocturnal voids) was investigated. In men treated with 50 µg of desmopressin, there was a −0.37 difference in reduction of nightly voids versus placebo ($P = .0003$). In men treated with 75 µg of desmopressin, there was a −0.41 difference in reduction of nightly voids versus placebo ($P < .0001$). In those treated with 50 µg, 0% had serum sodium from 126 mmol/L to 129 mmol/L, and 2% had serum sodium less than 125 mmol/L. In those treated with 75 µg, 4% had serum sodium from 126 mmol/L to 129 mmol/L, and 3% had serum sodium less than 125 mmol/L (Weiss et al., 2013b). From these data, it could be concluded that 50 µg of desmopressin melt may be the lowest therapeutically beneficial dose for men. In a related study, 261 women (19 to 87 years of age) with an average of three voids per night were given 25 µg of desmopressin ODT. Desmopressin ODT reduced nocturia by −1.46 (treatment difference vs. placebo: −0.22; $P = .028$) and increased odds of a 33% or greater response (from baseline nocturia severity) versus placebo by 85% (OR 1.85; $P = .006$) at month 3. This low dose of desmopressin melt increased mean time to first nocturnal void by 155 minutes (treatment difference vs. placebo: 49 min; $P = .003$) and reduced NUV by 235 mL (treatment difference vs. placebo: 83 mL; $P = .003$) at month 3. There were no serum sodium drops less than 125 mmol/L or treatment withdrawals as a result of hyponatremia (Sand et al., 2013).

Most recently, Noctiva nasal spray underwent FDA testing. Noctiva is desmopressin with cyclopentadecanolide (CPD), a cyclic fatty acid that works as a permeation enhancer. Three doses were tested: 0.75 µg, 1.0 µg, and 1.5 µg. Nadir serum sodium levels were studied to see what percentage of each cohort experienced hyponatremia (a serum sodium of 126 to 129 mmol/L with symptoms or a serum sodium of ≤125 mmol/L with or without symptoms). It was found that 0.4% of patients receiving placebo, 1% of patients receiving 0.75 µg, 2.7% of patients receiving 1.0 µg, and 4.3% of patients receiving 1.5 µg developed hyponatremia. Gender was not a risk factor for hyponatremia. The FDA approved Noctiva for adults with nocturnal polyuria who wake at least 2 times per night to void. The recommended dose for patients younger than 65 years of age is 1.5 µg. For patients 65 years of age and older, it is recommended that they start at 0.75 µg and have their dosage titrated up as needed, provided that their serum sodium remains normal (Noctiva, 2015).

Women appear to be more sensitive (by a factor of at least 2) to desmopressin than men in terms of effects on nocturnal urine production (Juul et al., 2011) **and duration of action** (Yamaguchi et al, 2013). This may be because the gene for the V_2 receptor is located on the X chromosome. It is hypothesized that the duplicated gene for V_2 in women results in less inactivation and thus a greater response to desmopressin. The phenomenon of gender differential sensitivity to desmopressin may explain why women seem to fare as well with a lower dose of the melt preparation than men (25 µg vs. 50 µg minimum effective dosages, respectively, based on the most recent studies as described herein).

Bae et al. demonstrated that desmopressin is a useful treatment in men with nocturia refractory to treatment with α-blockers (Bae et al., 2013). There were 216 patients enrolled in this study (76% with nocturnal polyuria, 7.2% with decreased nocturnal bladder capacity, and 16.8% with mixed cause). The number of nocturnal voids decreased from a mean of 7.0 to 5.7 episodes for 3 days at the 24-week visit.

In summary, when considering the use of desmopressin to treat nocturia, voiding diary analysis should immediately follow a urologic history and physical examination. Patients found to have global polyuria should be excluded for further evaluation. Patients with low volumes per void and no nocturnal polyuria may need “urologic” nonantidiuretic treatment approaches. **Current thinking is that desmopressin would be the most appropriate therapy for patients with nocturia related to nocturnal polyuria.** There is a gender sensitivity differential between genders (men appear to require a higher dose than women). Even though the risk for hyponatremia is less than 1% in those younger than 65 years of age and 8% in those older than 65 years of age, it is always wise to obtain a baseline serum sodium before commencing therapy. Desmopressin should not be given to elderly patients (>65 years of age) with baseline hyponatremia. It is advisable to monitor the serum sodium within 7 days and then 28 days after initial or incremental dosing, then continuing to check sodium levels every 6 months or more often as indicated. Table 119.4 presents a complete summary of medications used to treat nocturnal polyuria.

TABLE 119.4

Summary of Pharmacotherapeutic Agents Used to Treat Nocturnal Polyuria

DRUG NAME	DOSE	SIDE EFFECT(S)	CONTRAINDICATION(S)
Furosemide[a]	40 mg PO 6 h before sleep (Dose range 20–80 mg PO in adults. The study mentioned in this text used only 40 mg in the context of nocturia.)	Anorexia Nausea/vomiting Constipation Cramping Diarrhea Blurred vision Hearing loss Tinnitus Headache Orthostatic hypotension Hypokalemia Dehydration Metabolic alkalosis Muscle cramps SLE exacerbation	Hypersensitivity Anuria Hepatic coma Hypovolemia Severe hypokalemia
Imipramine[a]	10 mg, 25 mg, 50 mg (Dose range: 10–75 mg PO qhs)	Prolongs PR interval Prolongs QRS interval Prolongs QTc interval Increases heart rate Lowers T-wave amplitude Torsades de pointes Sudden death	Hypersensitivity Usage of MAOI within 14 days Acute recovery period after MI
Desmopressin[a]	Intranasal: 10 µg/spray; max 40 µg/day (central DI indication only) Noctiva[b]	Water intoxication Hyponatremia Flushing Diarrhea	Hypersensitivity CrCl <50 mL/min Hyponatremia History of hyponatremia Von Willebrand disease, type

	Starting dose: 1.5 µg for patients <65 years. For patients ≥65 or <65 years at increased risk for hyponatremia, starting dose: 0.75 µg Oral: 0.1-mg tablets; max 0.6 mg/day for PNE Melt: 60-, 120-, 240-µg melt tabs Melt “low dose”: 25 µg (women) and 50–100 µg (men)	Mild abdominal cramps Nausea Increased SGOT Thrombosis Cough Dyspnea Drowsiness Dizziness Headache Abnormal thinking Seizures	IIB Polydipsia Uncontrolled HTN Concomitant use of loop diuretics Concomitant use of systemic or inhaled glucocorticoids Known or suspected SIADH secretion

Diminished Global and Nocturnal Bladder Capacity

Causes

Diminished bladder capacity has many “urologic” causes, including infravesical obstruction, idiopathic nocturnal detrusor overactivity (NDO), neurogenic bladder, cystitis (bacterial, interstitial, tuberculous, radiation), and cancer of the bladder, prostate, or urethra. NDO occurs in association with nocturia in most patients with detrusor overactivity plus overactive bladder (OAB). NDO is not a normal concomitant of sleep, is not caused by sleep disturbance, and is not linked to nocturnal polyuria (Krystal et al., 2010). Additional causes of low global or nocturnal bladder capacity include learned voiding dysfunction, anxiety disorders, bladder calculi, ureteral calculi, and drugs such as xanthines (caffeine, theophylline) and β-blockers (Weiss, 2012). Low bladder compliance is also a risk factor for nocturia severity (Tsui et al., 2013).

Management

Treating bladder outlet obstruction (BOO) is thought to improve nocturia by lowering postvoid residual (PVR) volume, increasing functional bladder capacity, and reducing global urinary frequency. Reducing BOO also diminishes input from afferents in the bladder neck and the prostatic urethra (Cumming and Chisholm, 1992; Housami and Abrams, 2008; Margel et al., 2007). Tamsulosin therapy and transurethral resection of prostate (TURP) significantly reduced the number of episodes of nocturia in 17.9% and 32.2% of patients, respectively (Yoshimura et al., 2003), and by an average of 1.3 episodes per night in patients treated with TURP (Antunes et al., 2009). Outlet reduction also may act by increasing hours of uninterrupted sleep, with commensurate benefit to nocturia-specific quality of life. In patients who underwent **simple prostatectomy,** nocturia episodes decreased from a baseline of 3.4 to 2.6, 2 to 3 months postoperatively ($P < .001$) and hours of uninterrupted sleep increased from 1.83 at baseline to 2.74, 2 to 3 months postoperatively ($P < .001$) (Margel et al., 2007). In a retrospective analysis of 1258 men, improvement in nocturia-related quality of life was studied after various forms of treatment for BPH, including watchful waiting, α-blockers, TURP, and transurethral microwave treatment (TUMT). After 6 to 12 months, watchful waiting, α-blockers, TURP, and TUMT yielded reduction in nocturia episodes by 7%, 17%, 75%, and 32%, respectively. Improvements in nocturia-related quality of life were most strongly associated with treatment-associated declines in nocturia severity (van Dijk et al., 2010). Greenlight photoselective vaporization of the prostate has shown similar success to that of TURP in reducing BOO and improving nocturia (Cho et al., 2012). Other reports point out that nocturia still persists despite bladder outlet–reducing surgery. The third national health and nutrition examination survey (NHANES III) in the United States showed that among those who undergo TURP, nocturia (≥ two voids per night) persists for 41% of men 60 to 69 years of age and 50% of men older than 70 years of age (Platz et al., 2002).

TURP appears to be superior to tamsulosin for treatment of BPH-related nocturia. In a single-center study, 66 men with LUTS (mean age = 68.9 years) were randomized to receive **TURP or tamsulosin 0.4 mg orally at bedtime** for management of nocturia. Nocturia severity was assessed at baseline, 3 months, and 1 year. TURP was associated with a significant improvement compared with tamsulosin in the number of nocturnal awakenings, IPSS, International Consultation on Incontinence Questionnaire Nocturia (ICIQ-N) scores, and ICIQ-N Quality of Life (N-QoL) scores. Hours of uninterrupted sleep increased in both groups but were not statistically different (Simaioforidis et al., 2011). Newer-generation treatments for LUTS secondary to BPH such as Rezum aquablation, mechanical stenting (UroLift), and prostate artery embolization are all alternatives to traditional pharmacotherapy and less invasive alternatives to TURP (Pham and Sharma, 2018). However, none of these modalities have been proven more efficacious than TURP at improving LUTS, specifically nocturia.

A secondary analysis of the Department of Veterans Affairs Cooperative Study Trial studied the changes in nocturia in a cohort of 1078 men with BPH who were randomly assigned to receive **terazosin, finasteride, combination, or placebo.** Overall, episodes of nocturia decreased from a baseline mean of 2.5 to 1.8, 2.1, 2.0, and 2.1 episodes in the terazosin, finasteride, combination, and placebo groups, respectively. Mean reduction of nocturia episodes from treatment with terazosin alone was significantly different from that with treatment with combination therapy ($P = .03$), finasteride ($P = .0001$), and placebo ($P = .0001$). Terazosin and combination therapy reduced the number of nocturia episodes in men with BPH, although the advantage of terazosin over placebo was only a net reduction of 0.3 episode (Johnson et al., 2003).

In a 12-week randomized, controlled study, 850 patients were given 4 mg **tolterodine extended release** (Tolt ER) or placebo once daily 4 hours before going to bed. All subjects had eight or more micturitions per 24 hours with or without urge incontinence and nocturia (mean of 2.5 episodes per night). Tolt ER did not significantly reduce the total number of nocturnal micturitions; however, it did significantly reduce OAB-related and severe OAB-related nocturnal micturitions versus placebo. Tolt ER did not affect non-OAB nocturnal micturitions (Rackley et al., 2006). The suggestion here was that antimuscarinic therapy would benefit nocturic voids that are characterized by severe urgency.

In a randomized, controlled trial of 658 patients at 52 sites, patients were given either placebo or **trospium chloride** 20 mg twice daily. This was a 12-week, multicenter, parallel, double-blind, placebo-controlled study. After 12 weeks, a significant decrease was found in the mean number of nocturic episodes per night: 0.29 episode for placebo versus 0.57 episode for drug (baseline was two episodes per night) (Rudy et al., 2006).

Fesoterodine significantly improved all diary end points compared with placebo except for nocturnal voids and nocturnal urgency episodes (Dmochowski et al., 2010; Herschorn et al., 2010; Nitti et al., 2007). However, in a study powered to determine the effect of fesoterodine on nocturnal urgency as a primary end point, **fesoterodine** did decrease the number of nocturnal urgency episodes and the number of nocturnal voids when compared with placebo. This particular study looked at change from baseline to week 12 in the number of nocturnal urgency episodes per 24 hours. Urgency was defined as an intense and/or sudden need to urinate. The subject rated the feeling of urgency associated with each micturition episode using the 5-point Urinary Sensation Scale (USS) (Coyne et al., 2011), in which 1 = no feeling of urgency and 5 = unable to hold and leaked urine. Nocturnal urgency episodes were defined as those with a USS rating of 3 or greater. The mean reduction from baseline to week 12 in nocturnal urgency episodes per 24 hours was statistically significantly greater with fesoterodine than placebo (−1.29 vs. −1.06, $P = .0030$). Mean reduction from baseline to week 12 in nocturnal micturitions per 24 hours was significantly greater with fesoterodine than placebo (−1.02 vs. −0.84, $P = .0112$) (Weiss et al., 2013a).

A prospective randomized trial was conducted with 2583 men with one or more episodes of nocturia at baseline who were treated with doxazosin, finasteride, combination therapy (doxazosin + finasteride), or placebo. Treatment effectiveness was measured by a self-reported number of nocturia episodes at 1 and 4 years after treatment. After 1 year, mean nocturia was reduced by 0.35, 0.40, 0.54, and 0.58 in the placebo, finasteride, doxazosin, and combination groups, respectively; reductions with combination therapy and with doxazosin were statistically greater than with placebo ($P < .05$). After 4 years, the number of nocturia episodes was also significantly reduced in patients treated with doxazosin and combination therapy versus placebo ($P < .05$). In a subgroup of men older than 70 years of age ($n = 495$), all of the drugs significantly reduced nocturia at 1 year (finasteride 0.29, doxazosin 0.46, and combination 0.42) compared with placebo (0.11, $P < .05$). This study confirmed that α-blockers alone are as effective as α-blockers in combination with 5α-reductase inhibitors (5-ARIs) for treatment of nocturia (Johnson et al., 2007).

A randomized, double-blind, placebo-controlled study was carried out in which patients were assigned to one of four groups for 12 weeks: placebo ($n = 222$), 4 mg tolterodine extended release (Tolt ER, $n = 217$), 0.4 mg tamsulosin ($n = 215$), and combination 4 mg Tolt ER + 0.4 mg tamsulosin ($n = 225$). The combination of Tolt ER + tamsulosin significantly reduced the number of micturitions per night versus placebo (−0.59 vs. −0.39, $P = .02$) (Kaplan et al., 2006).

In conclusion, α-blockers, 5-ARIs, antimuscarinics, and antimuscarinics plus α-blockers have been found to have a statistically significant reduction

in nocturia episodes, but clinical significance appears to be minimal. When 5-ARIs and α-blockers are used in combination, they have the same degree of success as α-blockers alone. The optimal patients to treat with medications that target the bladder and the prostate appear to be those who have a large number of nocturia episodes (mostly resulting from severe urgency).

There have also been various alternative treatments for nocturia, including cyclooxygenase-2 inhibitors combined with α-blockers (Gorgel et al., 2013), sedatives (Song and Ku, 2007; Sugaya et al., 2007), melatonin (Drake et al., 2004; Sugaya et al., 2007), and phytotherapy. A systematic review of 1562 men from 18 randomized controlled trials examined the effect of *Pygeum africanum* on various BPH symptoms, including nocturia. There was no comparison of *P. africanum* to other pharmacologic treatments for BPH, including α-blockers and 5-ARIs. Compared with men taking placebo, those taking *P. africanum* reported a 19% reduction in nocturia (weighted mean difference [WMD] of −0.9 times per evening, $P > .05$) (Wilt et al., 1998).

Another phytotherapeutic, Cernilton, is prepared from the rye-grass pollen *Secale cereale*. A systematic review was conducted to assess the efficacy of Cernilton on urinary symptoms in men with BPH. Cernilton reduced nocturia compared with placebo and another neutraceutical, Paraprost. Versus placebo, the weighted risk ratio for improvement of nocturia was 2.05 (95% CI = 1.41 to 3.00); thus those taking Cernilton were approximately two times more likely to have their nocturia improve over those taking placebo. Versus Paraprost, the WMD was −0.40 nocturic episodes per evening (95% CI = −0.73 to −0.07). Data were collected from a self-rated urinary symptom survey. The limitations of these trials were short duration, limited number of enrollees, gaps in reported outcomes, quality control of preparations, and lack of a proved active control (Wilt et al., 2011).

Mirabegron, a β_3-adrenergic agonist approved by the US Food and Drug Administration to treat OAB, showed an improvement in nocturia measured by the OAB symptom score at 3 and 6 months after beginning treatment in women older than 70 years of age who did not respond to anticholinergics (Nakanishi, 2013). For a complete list of medications used to treat diminished global or nocturnal bladder capacity, see Table 119.5.

TABLE 119.5

Pharmacotherapeutic Agents Used to Treat Diminished Global and Nocturnal Bladder Capacity

DRUG NAME	DOSE	SIDE EFFECT	CONTRAINDICATION(S)
Tamsulosin[a]	0.4 mg, 0.8 mg PO qhs	Orthostatic hypotension Syncope Dizziness Asthenia Somnolence Headache Insomnia Diarrhea Abnormal ejaculation Intraoperative floppy iris syndrome Rhinitis Pharyngitis Sinusitis Cough Priapism Back pain Chest pain	Hypersensitivity
Terazosin[a]	1–5 mg PO qhs Max dose: 20 mg/day	Headache Dizziness Somnolence Vertigo Asthenia Nervousness Depression Paresthesias Hypotension Palpitations Syncope Supraventricular tachycardia Atrial fibrillation Postural hypotension Weight gain Peripheral edema Thrombocytopenia Dyspnea Nasal congestion	Hypersensitivity

		Rhinitis Sinusitis Nausea Blurred vision Amblyopia Intraoperative floppy iris syndrome Impotence UTI Decreased libido Priapism	
Finasteride[a]	5 mg/day PO	Orthostatic/postural hypotension Peripheral edema Asthenia Headache Dizziness Somnolence Decreased libido Impotence Rhinitis Dyspnea Decreased ejaculate volume Gynecomastia Breast cancer	Hypersensitivity Women and children Pregnancy
Solifenacin[a]	5–10 mg/day PO	Dizziness Depression Dry mouth Constipation Nausea Colonic obstruction Severe fecal impaction Intestinal obstruction Dyspepsia Upper abdominal pain Vomiting Hypertension QT prolongation Torsades de pointes	Hypersensitivity Urinary retention Gastric retention Uncontrolled narrow-angle glaucoma Severe hepatic impairment

		Cough Blurred vision Dry eyes Urinary retention UTI Fatigue	
Tolterodine[a]	1–2 mg PO bid LA formulation: 2–4 mg/day PO	Dizziness Headache Somnolence Chest pain Dry mouth Constipation Dyspepsia Abnormal vision Xerophthalmia Urinary retention Dysuria Dry skin Arthralgia Sinusitis Weight gain Flulike symptoms Fatigue	Hypersensitivity Urinary retention Gastric retention Uncontrolled narrow-angle glaucoma Potassium salts
Trospium chloride[a]	Adults <75 years: 20 mg PO bid Adults >75 years: 20 mg PO qhs (based on tolerability)	Dry mouth Constipation Flatulence Abdominal pain Abdominal distention Dyspepsia Headache Fatigue Rash Stevens-Johnson syndrome Nasopharyngitis Dry eyes Nasal dryness Abnormal vision Urinary retention Rhabdomyolysis Fever	Hypersensitivity Urinary retention Gastric retention Uncontrolled narrow-angle glaucoma Severe renal impairment

		Heat stroke Influenza Anaphylaxis	
Fesoterodine[a]	4–8 mg/day PO If on potent CYP3A4 inhibitors: 4 mg/day PO	Dry mouth Constipation Nausea Abdominal pain Dyspepsia Gastroenteritis Cough Dry throat Upper respiratory tract infection Tachycardia Angina Chest pain QT prolongation Dysuria Urinary retention UTI Rash Dry eyes Back pain Edema Heat stroke	Hypersensitivity Urinary retention Gastric retention Uncontrolled narrow-angle glaucoma Severe hepatic impairment
Doxazosin[a]	Immediate release: 1–8 mg/day PO Extended release: 4–8 mg/day PO	Dizziness Headache Drowsiness Weakness Mental depression Syncope Vertigo Orthostatic hypotension Hypotension Arrhythmias Palpitations Edema Dyspnea Syncope Blurred vision Reddened sclera	Hypersensitivity

		Epistaxis Dry mouth Nasal congestion Rash Vomiting Diarrhea Nausea Abdominal cramps	
Mirabegron[b]	25–50 mg/day PO	Hypertension Urinary retention	Hypersensitivity

bid, Twice a day; *LA,* long-acting; *PO,* by mouth; *qhs,* at bedtime; *UTI,* urinary tract infection.

Several other treatments can also help reduce the number of nighttime voids. Onabotulinum toxin A (100 units) has been shown to significantly reduce nocturia episodes when compared with placebo in patients with OAB (Chapple et al., 2013; Nitti et al., 2013). Posterior tibial nerve stimulation (PTNS) can also significantly reduce nocturia in the OAB population (van Balken et al., 2001; van der Pal et al., 2006; Yoong et al., 2010).

Mixed Nocturnal Polyuria and Diminished Global and Nocturnal Bladder Capacity

In a review of 194 consecutive patients with nocturia, 13 (7%) had nocturnal polyuria (NPi >0.35), 111 (57%) had decreased nocturnal bladder capacity, and 70 (36%) had a “mixed” cause. Forty-five (23%) also had polyuria (defined as 24-hour urine output >2500 mL). Nocturnal polyuria was a significant component of nocturia in 43% of the patients. Thus the cause of nocturia was found to be multifactorial and often unrelated to an underlying urologic condition (Weiss et al., 1998). In a US veteran population of men 50 years of age and older, Vaughan et al. demonstrated a significant improvement in ANV ($P < .001$), bother ($P < .001$), time to initiating sleep ($P = .003$), time to return to sleep ($P = .03$), and quality of sleep ($P < .001$) after single or combined pharmacotherapy and/or behavioral modification to address the mixed etiologic category of nocturia (Vaughan et al., 2009). Behavior modification included reduced caffeine and alcohol intake, limited nighttime fluid intake, and improved sleep hygiene through moderate exercise and attention to room temperature, noise, and lighting. Additional interventions included early evening leg elevation and compression stockings if patients had bilateral lower extremity edema. Also, if patients had BPH-related symptoms (American Urological Association symptom score ≥8, maximum uroflow [Qmax] 4 to 15 mL/sec), terazosin was titrated as tolerated/needed to 10 mg daily. If patients reported eight or more voids in 24 hours, Tolt ER 2 to 4 mg daily was initiated. If return to sleep required 30 minutes or more after an awakening, zaleplon 5 mg nightly after the first nocturia episode between 11:00 PM and 3:00 AM was recommended. This proved to be a structured, multimodal approach with little risk (one trip to an emergency room for hypotension after taking terazosin) (Vaughan et al., 2009). Multicomponent treatment was further found to be an effective strategy to treat nocturia in a study by Johnson et al. (2013) in which men on α-blockers received individually titrated drug therapy (extended-release oxybutynin) or multicomponent behavioral treatment (pelvic floor muscle training, delayed voiding, and urge-suppression techniques). Participants with two or more episodes of nocturia at baseline showed larger changes with behavioral treatment compared with antimuscarinic therapy (mean reduction = 1.26 vs. 0.61, respectively; P = .008).

Polyuria

Etiology

Polyuria is defined as 24-hour urine output greater than 40 mL/kg. Once a steady state is reached, polyuria is associated with excessive oral intake of fluids (polydipsia). This results in urinary frequency both day and night because of the global overproduction of urine in excess of bladder capacity. Nocturia is often the manifesting symptom of patients with polyuria of any cause. Hence, it behooves the urologist to understand both its cause and diagnostic measures to sort out its various causes. Common underpinnings of polyuria include uncontrolled diabetes mellitus, diabetes insipidus, and primary polydipsia (dipsogenic, caused by an abnormality of the thirst mechanism, and psychogenic).

Diabetes insipidus is a disorder of water balance in which inappropriate excretion of water leads to polydipsia in an effort to prevent circulatory collapse. Diabetes insipidus can be central or nephrogenic. Central diabetes insipidus occurs when there is a deficiency in the synthesis or secretion of endogenous ADH. This can be caused by loss of neurosecretory neurons in the hypothalamus or the posterior pituitary gland as a result of trauma, primary pituitary tumors (e.g., craniopharyngioma), metastatic disease (e.g., breast, lung), infiltrative disease (e.g., sarcoid), infarction (e.g., Sheehan syndrome postpartum), or infection (e.g., tuberculosis, meningitis), or it can be idiopathic (Shapiro and Weiss, 2012). Nephrogenic diabetes insipidus is diuresis in the setting of normal ADH secretion, but the kidneys do not respond appropriately to the hormone, as in some patients with chronic kidney disease. Some extrarenal causes of diabetes insipidus include PGE_2, ANP, hypercalcemia, hypokalemia, lithium, and certain tetracyclines. This mechanism may explain how nonsteroidal anti-inflammatory drugs can improve nocturia, because of the effect of these drugs in blocking PGE_2-mediated diuresis (Araki et al., 2004).

The diagnostic algorithm for polyuria begins with an overnight water-deprivation test (OWDT). To perform an OWDT, the patient is told not to drink anything during the night. It is normal if the first-morning urine osmolality is greater than 800 mOsm/kg H_2O. Normal implies that there is an appropriate secretion of ADH and an appropriate renal response. If the OWDT is normal, polyuria is a result of primary polydipsia (neurogenic or dipsogenic). If the OWDT is abnormal, the patient has diabetes insipidus. To distinguish central from nephrogenic diabetes insipidus, a renal concentrating capacity test (RCCT) may be performed. The RCCT is performed by giving 40 µg of desmopressin intranasally or 0.4 mg orally. The patient's bladder is emptied, and urine osmolality is tested 3 to 5 hours later. Water is restricted for the first 12 hours after the drug is administered. The RCCT is normal if the urine osmolality rises to at least 800 mOsm/kg H_2O (Weiss, 2012). If the RCCT is normal, the patient has central diabetes insipidus and can be treated with desmopressin replacement therapy. If the RCCT is abnormal, the patient has nephrogenic diabetes insipidus, which has no specific treatment unless external causative factors such as lithium can be stopped.

Management

Patients who have a 24-hour urine production greater than 30 mL/kg may benefit from water restriction during the day and night. Tani et al. (2014) showed that adjusting water and food intake so that 24-hour urine production is less than 30 mL/kg reduced NUV and nocturnal urinary frequency with no adverse events. This illustrates that guidance on water intake may be a safe and effective conservative lifestyle management strategy. Because primary thirst disorders are distinctly rare, a safety mechanism in recommending fluid intake restriction is to have patients drink only just enough to satisfy their thirst.

A patient with **primary (dipsogenic or psychogenic) polydipsia** will have normal urine osmolality on water deprivation tests. **Dipsogenic polydipsia** is associated with a history of a central neurologic abnormality such as a history of brain trauma or radiation. Psychogenic polydipsia is a long-term behavioral or psychiatric disorder. It is important to identify the cause of a patient's polyuria to treat it effectively. For example, if a patient with polyuria has diabetes mellitus, controlling glycosuria may improve the polyuria. Central diabetes insipidus may be treated with synthetic vasopressin analogues. Patients without diabetes insipidus who are found to have polydipsia and are compulsive water drinkers may benefit from psychotherapy (Weiss, 2012). Nocturia as a manifesting complaint is expected to benefit from appropriate therapy for polyuria.

Key Points: Evaluation and Management of Nocturia

- Classification of nocturia using a frequency-volume chart yields up to 17 different underlying medical conditions that may potentially contribute to its genesis.
- OSA is a common cause of nocturnal polyuria.
- The normal circadian pattern of nocturnal urine production is age-dependent.
- Treating nocturnal polyuria should focus on underlying contributing medical comorbidities.
- There are many causes of diminished bladder capacity, including infravesical obstruction, idiopathic nocturnal detrusor overactivity, neurogenic bladder, cystitis (bacterial, interstitial, tuberculous, radiation), and cancer of the bladder, prostate, or urethra.
- Treating BOO is thought to improve nocturia by lowering PVR volume, increasing functional bladder capacity, and reducing overall urinary frequency.
- α-Blockers, 5-ARIs, antimuscarinics, and antimuscarinics plus α-blockers have been found to result in statistically but questionably clinically significant reductions in nocturia episodes.
- When 5-ARIs and α-blockers are used in combination, they have the same

degree of success as α-blockers alone.

- The optimal group to treat with medications that target the bladder and the prostate appear to be those who have a large number of nocturia episodes (mostly as a response to severe urgency) unrelated to nocturnal polyuria.
- Polyuria is defined as 24-hour urine output greater than 40 mL/kg and thus must be diagnosed through use of frequency-volume charts. Treatment of conditions underlying polyuria should benefit nocturia.
- Patients with nocturnal polyuria unrelated to specific causes such as peripheral edema, cardiopulmonary disease, or sleep apnea may benefit from empiric treatment with desmopressin.
- Desmopressin is associated with increased risk for clinically significant hyponatremia in elderly patients (>65 years) and those with borderline pretreatment hyponatremia, impaired renal function, and small body habitus.

Pharmacologic Management of Lower Urinary Tract Storage and Emptying Failure

Karl-Erik Andersson MD, PhD

Introduction

The function of the lower urinary tract (LUT) is to effect efficient and low-pressure bladder filling, low-pressure urine storage with normal sensation and perfect continence, and periodic complete voluntary emptying, again at low pressure. The structures involved include the smooth musculature of the bladder and the bladder outlet, and striated muscle, both intrinsic (to the bladder outlet) and extrinsic (the striated musculature surrounding the bladder outlet and the striated musculature of the pelvic floor). These component structures are controlled by a complex interplay among the central and peripheral nervous systems and local regulatory factors. **Pharmacologic alteration of LUT function can occur at any point along the afferent or efferent limb of this complex neuromuscular cascade by receptor activation or stimulation or blockade, by affecting the concentration of neurotransmitter at an activation site, or by stimulating or inhibiting signal transduction mechanisms** (Andersson and Wein, 2004; Andersson et al., 2009, 2013a, 2017; Birder et al., 2009; Fry et al., 2009; see also Chapter 69).

This chapter considers the pharmacologic management of bladder filling and storage and bladder emptying and voiding dysfunction. The conceptual basis of the organization is that of the expanded functional classification shown in Boxes 70.1 and 70.2 in Chapter 70 and the division of therapies in the relatively simple manner of those that facilitate urine storage and bladder filling and those that facilitate bladder emptying and voiding (see Boxes 70.3 and 70.4 in Chapter 70). Although the principles expressed are generally applicable to patients of all ages, specifics concerning usage in the pediatric age groups and in the elderly are considered in detail in Chapters 141 and 142. Specific information regarding the pharmacologic management of LUT dysfunction secondary to obstruction by benign prostatic enlargement (BPE) is considered in detail in Chapter 103, whereas drug therapy for the treatment of bladder and pelvic pain disorders is considered in detail in Chapters 13 and 14.

As an apology in explanation to significant contributors to the field whose works have not been specifically referenced by name as frequently as they could have been, please note that the citations have been chosen primarily because of their comprehensive review or specific informational content and not because of originality or initial publication on a particular subject, except where noted.

Pharmacologic Therapy to Facilitate Bladder Filling and Urine Storage

Inhibiting Bladder Contractility, Decreasing Sensory Input, Increasing Bladder Capacity

Bladder Contraction

The major portion of the neurohumoral stimulus for physiologic bladder contraction is acetylcholine (ACh)-induced stimulation of postganglionic parasympathetic muscarinic cholinergic receptor sites in the bladder (detrusor smooth muscle and possibly other sites) (see Chapter 69). **Atropine and atropine-like agents will depress normal bladder contractions and involuntary bladder contractions (detrusor overactivity [DO]) of any cause** (Andersson, 1988, 1993; Andersson and Wein, 2004)**. In patients with involuntary contractions, the volume to the first DO will usually be increased, the amplitude of the contraction decreased, and the total bladder capacity increased** (Jensen, 1981).

It has been stated that bladder compliance in normal individuals and in those with neurogenic detrusor overactivity (NDO) (Abrams et al., 2002), in whom the initial slope of the filling curve on cystometry is normal before the involuntary contraction, does not seem to be significantly altered by antimuscarinic agents and that the effect of pure antimuscarinics in patients who exhibit only decreased compliance had not been well studied. Regarding the subject of bladder tone during filling, Andersson (1999a, 1999b, 2004, 2011b) and Andersson and Yoshida (2003) have pointed out that although it is widely accepted that there is normally no sacral parasympathetic outflow to the bladder during filling, antimuscarinic drugs increase, and anticholinesterase inhibitors decrease, bladder capacity. **Because antimuscarinic drugs do seem to affect the sensation of urgency during filling, this suggests an ongoing ACh-mediated stimulation of detrusor tone (see later). If this is correct, agents that inhibit ACh release or activity would be expected to contribute to bladder relaxation or the maintenance of low bladder tone during filling with a consequent decrease in filling and storage symptomatology unrelated to the occurrence of DO. Outlet resistance, at least as reflected by urethral pressure measurements, does not seem to be clinically affected.**

Although the antimuscarinic agents usually produce significant clinical improvement in patients with DO and associated symptoms, they typically produce only partial inhibition. In many animal models, atropine only partially antagonizes the response of the whole bladder to pelvic nerve stimulation and of bladder strips to field stimulation, although it does completely inhibit the response of bladder smooth muscle to exogenous cholinergic stimulation. This phenomenon, which is called *atropine resistance,* is secondary to release of a transmitter other than ACh (Andersson, 1993; Andersson and Wein, 2004; Andersson et al., 1999; see Chapter 69). Atropine resistance is the most common hypothesis invoked to explain the clinical difficulty in eradicating DO with antimuscarinic agents alone, and it is also invoked to support the rationale of combined treatment of DO with agents that have different mechanisms of action (Andersson, 2006).

Andersson and Wein (2004) cite references stating that atropine resistance seems to be of little importance in normal human bladder muscle, but point out that atropine-resistant (nonadrenergic, noncholinergic [NANC]) contractions have been reported in human detrusor smooth muscle and in morphologically and/or functionally changed bladders in individuals with various types of voiding dysfunction. Thus, **the importance or unimportance of an atropine-resistant component to detrusor contraction in the treatment of DO in humans remains to be established.**

Muscarinic Receptors

In the human bladder, where the mRNAs for all the five pharmacologically defined muscarinic receptors, M_1 to M_5, have been demonstrated (Abrams et al., 2006a; Andersson, 2011a; Giglio and Tobin, 2009; Sigala et al., 2002)**, there is a predominance of mRNAs encoding M_2 and M_3 receptors** (Abrams et al., 2006a; Andersson, 2011a; Giglio and Tobin, 2009; Sigala et al., 2002; Yamaguchi et al., 1996). This seems to be the case also in the animal species investigated (Andersson and Arner, 2004; Chess-Williams, 2002; Hegde and Eglen, 1999). **Both M_2 and M_3 receptors can be found on detrusor muscle cells, where M_2 receptors predominate at least 3 : 1 over M_3 receptors, but also in other bladder structures, which may be of importance for detrusor activation. Thus, muscarinic receptors can be found on urothelial cells, on suburothelial nerves, and on other suburothelial structures, such as interstitial cells** (Andersson, 2011a; Bschleipfer et al., 2007; Chess-Williams, 2002; Giglio and Tobin, 2009; Gillespie, 2004; Gillespie et al., 2003; Mansfield et al., 2005).

In human and animal detrusor, the M_3 receptors are believed to be the most important for contraction (Abrams et al., 2006a; Andersson, 1993, 2011a; Chess-Williams, 2002; Giglio and Tobin, 2009). No differences between genders could be demonstrated in rat and human bladders (Kories et al., 2003). **The functional role for the M_2 receptors has not been clarified,** and even in M_3 receptor knockout (KO) mice they seem responsible for less than 5% of the carbachol-mediated detrusor contraction (Matsui et al., 2000). Stimulation of M_2 receptors has been shown to oppose sympathetically (β-adrenoceptor [β-AR]) mediated smooth muscle relaxation (Hegde et al., 1997). However, based on animal experiments, M_2 receptors have been suggested to directly contribute to contraction of the bladder in certain disease states (denervation, outflow obstruction). Experiments on human detrusor muscle by Stevens et al. (2007) could not confirm this, however. Pontari et al. (2004) analyzed bladder muscle specimens from patients with neurogenic bladder dysfunction to determine whether the muscarinic receptor subtype mediating contraction shifts from the M_3 to M_2 receptor subtype, as found in the denervated, hypertrophied rat bladder. They concluded that normal detrusor contraction is mediated by the M_3 receptor subtype, whereas contractions can be mediated by the M_2 receptors in patients with neurogenic bladder dysfunction.

Muscarinic receptors are coupled to G proteins, but the signal transduction systems may vary. **In general, M_1, M_3, and M_5 receptors are considered to couple preferentially to $G_{q/11}$, activating phosphoinositide hydrolysis, in turn leading to mobilization of intracellular calcium. M_2 and M_4 receptors couple to pertussis toxin–sensitive $G_{i/o}$, resulting in inhibition of adenylyl cyclase activity.** In the human detrusor, Schneider et al. (2004a), confirming that the muscarinic receptor subtype mediating carbachol-induced contraction is the M_3 receptor, also demonstrated that the phospholipase C inhibitor, U-73122, did not significantly affect carbachol-stimulated bladder contraction, despite blocking inositol trisphosphate (IP_3) generation. They concluded that carbachol-induced contraction of human urinary bladder is mediated via M_3 receptors and largely depends on Ca^{2+} entry through nifedipine-sensitive channels and activation of the Rho-kinase pathway. **Thus, it may be that the main pathways**

for muscarinic-receptor activation of the detrusor via M_3 receptors are calcium influx via L-type calcium channels, and increased sensitivity to calcium of the contractile machinery via inhibition of myosin light chain phosphatase through activation of Rho-kinase.

The **signaling mechanisms for the M_2 receptors are less clear than those for M_3 receptors.** As mentioned earlier, **M_2 receptor stimulation may oppose sympathetically induced smooth muscle relaxation, mediated by β-ARs via inhibition of adenylyl cyclase** (Hegde et al., 1997). In agreement with this, Matsui et al. (2003) suggested, based on results obtained in M_2 receptor KO mice, that a component of the contractile response to muscarinic agonists in smooth muscle involves an M_2 receptor–mediated inhibition of the relaxant effects of agents that increase cyclic adenosine monophosphate (cAMP) levels. M_2-receptor stimulation can also activate nonspecific cation channels and inhibit K_{ATP} channels through activation of protein kinase C (Bonev and Nelson, 1993; Kotlikoff et al., 1999).

Muscarinic receptors may also be located on the presynaptic nerve terminals and participate in the regulation of transmitter release. The inhibitory prejunctional muscarinic receptors have been classified as muscarinic M_2 in the rabbit (Tobin and Sjögren, 1995) and rat (Somogyi and de Groat, 1992) and M_4 in the guinea pig (Alberts, 1995) and in the human bladder (D'Agostino et al., 2000). Prejunctional facilitatory muscarinic receptors appear to be of the M_1 subtype in the bladders of rat, rabbit (Somogyi and de Groat, 1992; Tobin and Sjögren, 1995), and humans (Andersson, 2011b; Giglio and Tobin, 2009; Somogyi and de Groat, 1999). The muscarinic facilitatory mechanism seems to be upregulated in overactive bladders (OABs) from chronic spinal cord–transected rats. The facilitation in these preparations is primarily mediated by M_3 muscarinic receptors (Somogyi and de Groat, 1999).

The relative roles of the different presynaptic and postsynaptic receptor subtypes in normal and abnormal bladder function still require clarification, and thus speculation regarding optimal drug therapy based only on in vitro receptor selectivity profiles represents, at the very least, a gross oversimplification of assumptions regarding the muscarinic regulation of bladder function. The muscarinic receptor functions may be changed in different urologic disorders, such as outflow obstruction, neurogenic bladders, DO without overt neurogenic cause, and diabetes (Andersson, 2000a, 2011b). **However, it is not always clear what the changes mean in terms of changes in detrusor function.**

In general, all drug therapy for LUT dysfunction is hindered by a concept that can be expressed in one word: *uroselectivity* (Andersson, 1998)**. The clinical usefulness of available antimuscarinic agents is limited by their lack of selectivity, responsible for the classic peripheral antimuscarinic side effects of dry mouth, constipation, blurred vision, and increase in heart rate (HR) and for the effects on cognitive functions (Table 120.1).** Although M_3-receptor selective agents have the potential to eliminate some of these side effects, it would appear that the M_3 receptors in tissues of the LUT are identical to those elsewhere in the body (Caulfield and Birdsall, 1998). It may be speculated, however, that there is some heterogeneity among M_3 receptors, and this has prompted many pharmaceutical companies to continue to search for the "ideal" antimuscarinic agent to treat DO, one that would be relatively selective for muscarinic receptors involved in the regulation of bladder contraction. Receptor selectivity, however, is not the only basis on which a drug may be uroselective. From a clinical standpoint, it would seem particularly important to be able to describe in relative terms the ratio between a drug dose required for a desired therapeutic action and the dose that produces side effects. A differential effect could be based not only on receptor selectivity but also on other known and as yet undefined physiologic, pharmacologic, or metabolic characteristics. Organ selectivity would thus seem to be the "holy grail" of such therapy. The same problematic set of concepts applies to virtually all drugs used for the treatment of LUT dysfunction.

TABLE 120.1

Muscarinic Receptors: Distribution and Function

REGION	SUBTYPE OF MUSCARINIC RECEPTOR	FUNCTION
Bladder	$M_2 > M_3$ (3 : 1)	M_3: mediates human detrusor contraction
Salivary glands, parotid gland	M_1, M_3	M_1: high-viscosity lubrication M_3: salivation
Gastrointestinal tract	$M_2 > M_3$ (4 : 1)	M_3: stimulation of gastrointestinal motility

Brain	M_1 to M_5 (M_3 sparse)	Involved in higher cognitive processes such as learning and memory (mostly M_1)
Eye	M_1 to M_5 (M_3 predominates)	Controls iris sphincter contraction
Heart	M_2	Modulates pacemaker activity, atrioventricular conduction, and the force of contraction

Prevalence of Lower Urinary Tract Symptoms

The prevalence of lower urinary tract symptoms (LUTS), including OAB syndrome, varies with the criteria for diagnosis. According to Irwin et al. (2006), using the 2002 International Continence Society (ICS) definition, the overall prevalence of OAB was 11.8% (the EPIC study). The rates were similar in men and women and increased with age. A similar study by Herschorn et al. (2008) found the OAB prevalence to be 13% in Canadian men and 14% in women. Irwin et al. (2011) estimated and predicted the worldwide and regional prevalence of LUTS, OAB, urinary incontinence (UI), and LUTS suggestive of bladder outlet obstruction (LUTS/BOO) in 2008, 2013, and 2018 based on current ICS symptom definitions in adults older than 20 years of age. An estimated 45.2%, 10.7%, 8.2%, and 21.5% of the 2008 worldwide population (4.3 billion) were affected by at least one LUTS, OAB, UI, and LUTS/BOO, respectively. By 2018, an estimated 2.3 billion individuals will be affected by at least one LUTS (18.4% increase), 546 million by OAB (20.1%), 423 million by UI (21.6%), and 1.1 billion by LUTS/BOO (18.5%).

LUTS may be the result of several different mechanisms, both myogenic and neurologic (Banakhar et al., 2012; Birder et al., 2009; Koelbl et al., 2009; Morrison et al., 2002), and abundant drugs have been used for treatment. The 6th International Consultation on Incontinence assessed drugs used for treatment of incontinence (Andersson et al., 2017). The assessment criteria (Table 120.2) were based on the Oxford guidelines, and the drugs included are listed in Tables 120.3 and 120.4.

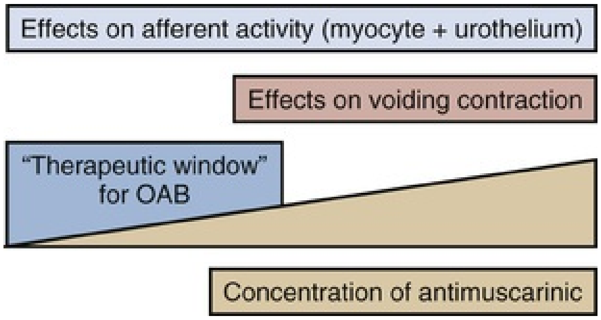
Antimuscarinic (Anticholinergic) Agents

Mechanism of Action.

For many years, antimuscarinic drugs have been the gold standard for

treatment of OAB. Still, the ways by which they exert their beneficial effect have not yet been established.

ACh stimulates both muscarinic and nicotinic receptors (Abrams and Andersson, 2007). Antimuscarinics block selectively muscarinic receptors. They are currently the mainstay of treatment of OAB symptoms, even if new therapeutic options have been introduced (Andersson et al., 2017). The **traditional view** is that in OAB and DO, the drugs act by blocking the muscarinic receptors on the detrusor muscle, which are stimulated by ACh, released from activated cholinergic (parasympathetic) nerves. Thereby, they decrease the ability of the bladder to contract. **However, antimuscarinic drugs act mainly during the storage phase, decreasing urgency and increasing bladder capacity, and during this phase, there is normally no parasympathetic input to the LUT** (Andersson, 2004; Morrison et al., 2002). Furthermore, antimuscarinics are usually competitive antagonists. This implies that when there is a massive release of ACh, as during micturition, the effects of the drugs should be decreased; otherwise the reduced ability of the detrusor to contract would eventually lead to urinary retention. Undeniably, high doses of antimuscarinics can produce urinary retention in humans, **but in the dose range used for beneficial effects in OAB and DO, there is little evidence for a significant reduction of the voiding contraction** (Finney et al., 2006) **(Fig. 120.1).** There is indirect clinical evidence for release of ACh during bladder filling in certain abnormal conditions. Smith et al. (1974) found that in patients with recent spinal cord injury (SCI), inhibition of ACh breakdown by use of cholinesterase inhibitors could increase resting tone and induce rhythmic contractions in the bladder. Yossepowitch et al. (2001) inhibited ACh breakdown with edrophonium in a series of patients with disturbed voiding or UI. They found a significant change in sensation and decreased bladder capacity, induction or amplification of involuntary detrusor contractions, or significantly decreased detrusor compliance in 78% of the patients with the symptom pattern of OAB, but in no patients without specific complaints suggesting DO. Thus, **during the storage phase, ACh may be released from both neuronal and non-neuronal sources** (e.g., the urothelium and suburothelium) **and directly or indirectly (by increasing detrusor smooth muscle tone) excite afferent nerves in the suburothelium and within the detrusor. There is also good experimental evidence that antimuscarinics act during the storage phase by decreasing the activity in afferent nerves (both C and Aδ fibers) from the bladder** (De Laet et al., 2006; Iijima et al., 2007).



Effects on afferent activity (myocyte + urothelium)
Effects on voiding contraction
"Therapeutic window" for OAB
Concentration of antimuscarinic

FIG. 120.1 Rationale for use of antimuscarinic agents in overactive bladder (OAB).

Muscarinic receptors are found on bladder urothelial cells, where their density can be even higher than in detrusor muscle. The role of the urothelium in bladder activation has attracted much interest (Andersson, 2002a, 2011b; Birder and Andersson, 2013; Birder and de Groat, 2007; Birder et al., 2009; de Groat, 2004; Giglio and Tobin, 2009), but whether the muscarinic receptors on urothelial cells can influence micturition has not yet been established. Yoshida et al. (2004, 2006, 2008) found that there is basal ACh release in human bladder. This release was resistant to tetrodotoxin and much diminished when the urothelium was removed; thus, the released ACh was probably of non-neuronal origin and at least partly generated by the urothelium. Thus, during the storage phase, ACh and adenosine triphosphate (ATP) may be released from both neuronal and non-neuronal sources (e.g., the urothelium) and directly or indirectly (by increasing detrusor smooth muscle tone) excite afferent nerves in the suburothelium and within the detrusor. These mechanisms may be important in the pathophysiology of OAB and represent possible targets for antimuscarinic drugs.

Pharmacologic Properties.

In general, antimuscarinics can be divided into tertiary and quaternary amines (Abrams and Andersson, 2007; Guay, 2003). They differ with regard to lipophilicity, molecular charge, and even molecular size, tertiary compounds typically having higher lipophilicity and lower or neutral charge than quaternary amines. **Atropine, darifenacin, fesoterodine (and its active metabolite 5-hydroxymethyl tolterodine [5-HMT]), imidafenacin, oxybutynin, propiverine, solifenacin, and tolterodine are tertiary amines. They are generally well absorbed from the gastrointestinal tract and should theoretically be able to pass into the central nervous system (CNS),** dependent on their individual physicochemical properties. **High lipophilicity, small molecular size, and less charge will increase the possibilities to pass**

the blood-brain barrier, but for some of the drugs, this is counteracted by active transport out of the CNS by P-glycoprotein. Quaternary ammonium compounds, such as propantheline and trospium, are not well absorbed, pass into the CNS to a limited extent, and have a low incidence of CNS side effects (Guay, 2003). They still produce well-known peripheral antimuscarinic side effects, such as accommodation paralysis, constipation, increase in HR, and dry mouth.

Many antimuscarinics are metabolized by the P450 enzyme system to active and/or inactive metabolites (Guay, 2003)**. The most commonly involved P450 enzymes are CYP2D6 and CYP3A4. The metabolic conversion creates a risk for drug-drug interactions, resulting in either reduced (enzyme induction) or increased (enzyme inhibition, substrate competition) plasma concentration or effect of the antimuscarinic and /or interacting drug.** Antimuscarinics secreted by the renal tubules (e.g., trospium) may theoretically be able to interfere with the elimination of other drugs using this mechanism.

Antimuscarinics are still the most widely used treatment for urgency and urgency incontinence (Andersson, 2004; Andersson et al., 2009, 2013a, 2017). However, currently used drugs lack selectivity for the bladder, and effects on other organ systems may result in side effects that limit their usefulness. For example, all antimuscarinic drugs are contraindicated in untreated narrow-angle glaucoma.

One way of avoiding many of the antimuscarinic side effects is to administer the drugs intravesically. However, this is practical in only a limited number of patients.

Clinical Use.

The clinical relevance of efficacy of antimuscarinic drugs relative to placebo has been questioned (Herbison et al., 2003). However, large meta-analyses of studies performed with the currently most widely used drugs clearly show that antimuscarinics are of significant clinical benefit (Chapple et al., 2005a, 2008a; Novara et al., 2008). It was recommended that because the pharmacologic profiles of each drug (see later) and dosages differ, these factors should be considered in making treatment choices.

The durability of the effects of antimuscarinics is not known, and the relapse rate of symptoms after discontinuation of treatment has not been systematically studied. In 173 women with OAB symptoms for longer than 6 months, Lee et al.

(2011) studied in a prospective, randomized, open-label trial what happened 3 months after the patients had been successfully treated for 1, 3, or 6 months. The relapse rate was 62%, and the request for retreatment was 65%, indirectly suggesting an efficacy of treatment.

None of the antimuscarinic drugs in common clinical use (darifenacin, fesoterodine, imidafenacin, oxybutynin, propiverine, solifenacin, tolterodine, or trospium) is ideal as a first-line treatment for *all* OAB or DO patients. Optimal treatment should be individualized, implying that the patient's comorbidities and concomitant medications, and the pharmacologic profiles of the different drugs, should be taken into consideration (Chapple et al., 2008a).

To compare the effects of different antimuscarinic drugs for OAB symptoms, Madhuvrata et al. (2012) analyzed 86 trials, 70 with parallel and 16 with crossover designs (31,249 adults), drawing attention to the significance of the adverse effect of dry mouth. They concluded that when the prescribing choice is between oral immediate-release (IR) oxybutynin or tolterodine, tolterodine might be preferred because of the reduced risk for dry mouth. Also, extended-release (ER) preparations of oxybutynin or tolterodine might be preferred to IR preparations because there is less risk for dry mouth. Comparing solifenacin and IR tolterodine, solifenacin might be preferred for better efficacy and less risk for dry mouth. Fesoterodine might be preferred over ER tolterodine for superior efficacy but has a higher risk for withdrawal because of adverse events in general, but in particular a higher risk for dry mouth.

Several studies have documented that **the persistence with prescribed antimuscarinic therapy for OAB is low** (Andersson, 2017a; Basra et al., 2008; Chapple et al., 2017; Kelleher et al., 2005; Sears et al., 2010; Wagg et al., 2012)**. The most common causes seem to be lack of efficacy and adverse effects.** In a two-phase survey, Benner et al. (2010) examined the reasons for discontinuing OAB pharmacotherapy. Expectations about treatment efficacy (46.2%) and side effects (21.1%) were the most important considerations. However, there is some evidence suggesting that the tolerability of the different antimuscarinics may differ. Wagg et al. (2012) analyzed prescription data for patients receiving antimuscarinics for treatment of OAB syndrome over a 12-month period (Wagg et al., 2012). At 12 months, they found that the proportions of patients still on their original treatment were as follows: solifenacin, 35%; tolterodine ER, 28%; propiverine, 27%; oxybutynin ER, 26%; trospium, 26%; tolterodine IR, 24%; oxybutynin IR, 22%; darifenacin, 17%; and flavoxate, 14%. The longest mean persistence was reported for solifenacin (187 days vs. 77 to 157 days for the other treatments). Gomes et al. (2012) compared the persistence of oxybutynin or tolterodine therapy among older patients who were newly prescribed one of these drugs. This was a retrospective cohort study of Ontarians 66 years of age and older. Persistence with treatment was defined on the basis of refills for the drug within a grace period equal to 50% of the prescription duration. The authors identified 31,996 patients who were newly treated with oxybutynin and 24,855 who were newly treated with tolterodine. After 2 years of follow-up, persistence on oxybutynin (9.4%) was significantly lower than that on tolterodine (13.6%, $P < .0001$). The median times to discontinuation of oxybutynin and tolterodine were 68 and 128 days, respectively. Kessler et al. (2011) analyzed 69 trials enrolling 26,229 patients with OAB. The aim was to compare adverse events of antimuscarinics using a network meta-analytic approach that overcomes shortcomings of conventional analyses. They found similar overall adverse event profiles for darifenacin, fesoterodine, transdermal oxybutynin, propiverine, solifenacin, tolterodine, and trospium chloride, but not for oxybutynin orally administered when currently used starting dosages were compared. They concluded that most currently used antimuscarinics seem to be equivalent first-choice drugs to start the treatment of OAB, except for oral oxybutynin doses of 10 mg/day or more, which may have more unfavorable adverse event profiles.

In a retrospective, longitudinal, observational study using anonymized data from the UK Clinical Practice Research Datalink GOLD database, Chapple et al. (2017) compared the persistence and adherence with the β_3-AR agonist, mirabegron, versus tolterodine ER and other antimuscarinics in routine clinical practice over a 12-month period. The study population included 21,996 patients, and the antimuscarinics studied, besides tolterodine ER, were darifenacin, fesoterodine, flavoxate, oxybutynin ER or IR, propiverine, solifenacin, tolterodine IR, and trospium chloride. The primary end point was persistence (time to discontinuation), and secondary end points included 12-month persistence rates and adherence, assessed using the medication possession ratio (MPR). The median time-to-discontinuation was significantly longer for mirabegron (169 days) compared with tolterodine ER (56 days) and other antimuscarinics (range, 30 to 78 days). The 12-month persistence rates, 38% and 20%, respectively, and MPR were also significantly greater with mirabegron than with all the antimuscarinics investigated.

Adverse Effects.

Even if the use of antimuscarinics is associated with many adverse effects, they are generally considered to be “safe” drugs. However, among the more serious concerns related to their use is the risk for cardiac adverse effects, particularly QT prolongation and induction of polymorphic ventricular tachycardia (torsades de pointes), and increases in HR (Andersson, 2011c; Andersson and Olshansky, 2007; Rosa et al., 2013). QT prolongation and its consequences are not related to blockade of muscarinic receptors, but rather linked to inhibition of the hERG potassium channel in the heart (Roden, 2004). Thus, QT prolongation is not a class effect of antimuscarinics. However, the experiences with terodiline, an antimuscarinic drug that caused torsades de pointes in patients (Connolly et al., 1991; Stewart et al., 1992), have placed the whole drug class under scrutiny.

The parasympathetic actions on the heart oppose the excitatory actions of the sympathetic nervous system and slow the HR. An elevated resting HR has been linked to overall increased morbidity and mortality, particularly in patients with cardiovascular disease. The prevalence of cardiovascular comorbidities was found to be significantly higher in patients with OAB compared with those without OAB (Andersson et al., 2010b). Because mean changes in HR reported in population studies might not be applicable to an individual patient, and particularly in patients at risk for cardiac disease, even moderate increases in HR might be harmful. The potential of the different antimuscarinic agents to increase HR and/or prolong the QT time has not been extensively explored for all agents in clinical use. Differences among drugs cannot be excluded, but risk assessments based on available evidence are not possible.

Another concern is that antimuscarinic drugs commonly used to treat OAB can be associated with CNS side effects including cognitive dysfunction, memory impairment, dizziness, fatigue, and headache. A growing body of literature has emerged to address these concerns. Antimuscarinic agents used to treat symptoms of overactive bladder may cross the blood-brain barrier and provoke subtle or not so subtle cognitive impairment (Callegari et al., 2011; Gray et al., 2015; Jacobsen et al., 2011; Pagoria et al., 2011; Wagg et al., 2010). Higher cumulative anticholinergic use was reported to be associated with an increased risk for dementia (Gray et al., 2015). Oxybutynin in particular, because of its small molecular size and increased propensity to cross the blood-brain barrier, has consistently shown potential to elicit cognitive impairment in new users after a single high dose of this agent or at steady state, and should be avoided in elderly patients (Donnellan et al., 1997; Katz et al., 1998; Kay et al., 2008, Wesnes et al., 2009). However, with the exception of oxybutynin IR, CNS-related side effects are not commonly found when investigated. The potential to cause CNS-related adverse effects may differ among drugs, but in the absence of comparative trials, relative risk assessments are not possible.

Taken together, increasing evidence suggests that with the exception of oxybutynin, use of the other antimuscarinic agents poses little or no cognitive risk to otherwise healthy older adults with symptoms of overactive bladder (Esin et al., 2015). However, the integrity of the blood-brain barrier may be compromised in many older adults with cerebrovascular disease, diabetes, or certain forms of dementia, with the results of studies in healthy older adults not generalizable to frailer individuals (Kay et al., 2005). In addition, long-term use of anticholinergic agents over months or years may yield more detrimental cognitive effects than single-dose or short-term use.

Antimuscarinics With “Pure” Action

Here, data on the different antimuscarinics are presented. These drugs are assumed to block only muscarinic receptors (motivating the term *pure*). The amount of information for the individual drugs varies, and so does the degree of detail from the different studies presented. However, the information has been chosen to give a reasonable efficacy and adverse-effect profile of each individual drug.

Atropine Sulfate.

Atropine (*dl*-hyoscyamine) is rarely used for treatment of OAB or DO because of its systemic side effects, which preclude its use as an oral treatment. However, in patients with NDO, intravesical atropine may be effective for increasing bladder capacity without causing systemic adverse effects, as shown in open pilot trials (Deaney et al., 1998; Enskat et al., 2001; Ekström et al., 1992; Fader et al., 2007; Glickman et al., 1995). It appears that intravesical atropine may be as effective as intravesical oxybutynin in patients with NDO (Fader et al., 2007).

The pharmacologically active antimuscarinic component of atropine is L-hyoscyamine. Although still used, few clinical studies are available to evaluate the antimuscarinic activity of L-hyoscyamine sulfate (Muskat et al., 1996). For assessment, see Table 120.3.

Darifenacin Hydrobromide.

Darifenacin is a tertiary amine with moderate lipophilicity, well absorbed

from the gastrointestinal tract after oral administration, and extensively metabolized in the liver by the cytochrome P450 isoforms CYP3A4 and CYP2D6, the latter saturating within the therapeutic range (Skerjanec, 2006). UK-148993, UK-73689, and UK-88862 are the three main circulating darifenacin metabolites, of which only UK-148993 is said to have significant antimuscarinic activity. However, available information suggests that various metabolites of darifenacin contribute little to its clinical effects (Michel and Hegde, 2006). The metabolism of darifenacin by CYP3A4 suggests that coadministration of a potent inhibitor of this enzyme (e.g., ketoconazole) may lead to an increase in the circulating concentration of darifenacin (Kerbusch et al., 2003).

Darifenacin is a relatively selective muscarinic M_3-receptor antagonist. In vitro, it is selective for human cloned muscarinic M_3 receptors relative to M_1, M_2, M_4, or M_5 receptors. Theoretically, drugs with selectivity for the M_3 receptor can be expected to have clinical efficacy in OAB and DO with reduction of the adverse events related to the blockade of other muscarinic receptor subtypes (Andersson, 2002b). However, the clinical efficacy and adverse effects of a drug are dependent not only on its profile of receptor affinity, but also on its pharmacokinetics, and on the importance of muscarinic receptors for a given organ function.

Darifenacin has been developed as a controlled-release formulation, which allows once-daily administration. Recommended doses are 7.5 and 15 mg/day. The clinical effectiveness of the drug has been documented in several randomized controlled trials (RCTs) (Abrams et al., 2008; Cardozo and Dixon, 2005; Chancellor et al., 2008b; Chapple et al., 2005b, 2007a; Dwyer et al., 2008; Foote et al., 2005; Haab et al., 2004, 2006; Hill et al., 2006; Steers et al., 2005; Zinner et al., 2006; for reviews, see Chapple et al., 2008a; Guay, 2005; Novara et al., 2008; Zinner, 2007). Haab et al. (2004) reported a multicenter, double-blind, placebo-controlled, parallel-group study that enrolled 561 patients (19 to 88 years; 85% female) with OAB symptoms for more than 6 months, and included some patients with prior exposure to antimuscarinic agents. After washout and a 2-week placebo run-in, patients were randomized (1 : 4 : 2 : 3) to once-daily oral darifenacin controlled-release tablets, 3.75 mg (*n* = 53), 7.5 mg (*n* = 229), or 15 mg (*n* = 115), or matching placebo (*n* = 164) for 12 weeks. Using an electronic diary during weeks 2, 6, and 12 (directly preceding clinic visits), patients recorded daily incontinence episodes, micturition frequency, bladder capacity (mean voided volume [MVV]), frequency of urgency, severity of urgency, incontinence episodes resulting in change of clothing or pads, and nocturnal awakenings caused by OAB. Tolerability data were evaluated from adverse event reports. Darifenacin 7.5 mg and 15 mg had a rapid onset of effect, with significant improvement compared with placebo being seen for most parameters at the first clinic visit (week 2). Darifenacin 7.5 mg and 15 mg were significantly superior to placebo for (median) improvements in micturition frequency (7.5 mg, −1.6; 15 mg, −1.7; placebo, −0.8), frequency of urgency per day (−2.0; −2.0; −0.9), and number of incontinence episodes leading to a change in clothing or pads (−4.0; −4.7; −2.0). There was no significant reduction in nocturnal awakenings caused by OAB. The most common adverse events were mild-to-moderate dry mouth and constipation, with a CNS and cardiac safety profile comparable to placebo. No patients withdrew from the study as a result of dry mouth, and discontinuation related to constipation was rare (0.6% for placebo vs. 0.9% for darifenacin).

In a dose titration study on 395 OAB patients, darifenacin, allowing individualized dosage (7.5 or 15 mg), was found to be effective and well-tolerated (Steers et al., 2005). A 2-year open-label extension study of these investigations (Haab et al., 2004; Steers et al., 2005) confirmed a favorable efficacy, tolerability, and safety profile (Haab et al., 2006).

Chapple et al. (2005b) reported a review of the pooled darifenacin data from the three phase III, multicenter, double-blind clinical trials in patients with OAB. After a 4-week washout and run-in period, 1059 adults (85% female) with symptoms of OAB (urgency incontinence, urgency, and frequency) for at least 6 months were randomized to once-daily oral treatment with darifenacin 7.5 mg (n = 337) or 15 mg (*n* = 334) or matching placebo (*n* = 388) for 12 weeks. Efficacy was evaluated using electronic patient diaries that recorded incontinence episodes (including those resulting in a change of clothing or pads), frequency and severity of urgency, micturition frequency, and bladder capacity (volume voided). Safety was evaluated by analysis of treatment-related adverse events, withdrawal rates, and laboratory tests. Relative to baseline, 12 weeks of treatment with darifenacin resulted in a dose-related significant reduction in median number of incontinence episodes per week (7.5 mg, −8.8 [−68.4%; placebo −54%, *P* < .004]; 15 mg, −10.6 [−76.8%; placebo 58%, *P* < .001]. Significant decreases in the frequency and severity of urgency, micturition frequency, and number of incontinence episodes resulting in a change of clothing or pads were also apparent, along with an increase in bladder capacity. Darifenacin was well tolerated. The most common treatment-related adverse events were dry mouth and constipation, although together these resulted in few discontinuations (darifenacin 7.5 mg, 0.6% of patients; darifenacin 15 mg, 2.1%; placebo, 0.3%). The incidence of CNS and cardiovascular adverse events were comparable to placebo. The results were confirmed in other RCTs, including also a pooled analysis of three phase III studies in older patients (≥65 years), showing that darifenacin (7.5 and 15 mg) had an excellent efficacy, tolerability, and safety profile (Foote et al., 2005; Hill et al., 2006; Zinner et al., 2005).

The time to effect with darifenacin was analyzed in a pooled analysis of efficacy and safety data from 1059 patients participating in three double-blind 12-week studies (Khullar et al., 2011). Darifenacin significantly improved all OAB symptoms as early as 6 to 8 days.

One of the most noticeable clinical effects of antimuscarinics is their ability to reduce urgency and allow patients to postpone micturition. A study was conducted to assess the effect of darifenacin on the warning time associated with urinary urgency. Warning time was defined as the time from the first sensation of urgency to the time of voluntary micturition or incontinence. This was a multicenter, randomized, double-blind, placebo-controlled study consisting of a 2-week washout, a 2-week medication-free run-in, and a 2-week treatment phase (Cardozo and Dixon, 2005). Warning time was defined as the time from the first sensation of urgency to voluntary micturition or incontinence and was recorded via an electronic event recorder at baseline (visit three) and study end (visit four) during a 6-hour clinic-based monitoring period, with the subject instructed to delay micturition for as long as possible. During each monitoring period, up to three urgency-void cycles were recorded. Of the 72 subjects who entered the study, 67 had warning time data recorded at both baseline and study end and were included in the primary efficacy analysis (32 on darifenacin, 35 on placebo). Darifenacin treatment resulted in a significant ($P <$ .004) increase in mean warning time, with a median increase of 4.3 minutes compared with placebo (darifenacin group from 4.4 to 1.8 minutes; placebo from 7.0 to −1.0 minutes). Overall, 47% of darifenacin-treated subjects compared with 20% receiving placebo achieved a 30% or greater increase in mean warning time. There were methodologic problems associated with this study; it used a dose of 30 mg (higher than the dose recommended for clinical use), the treatment period was short, it was conducted in a clinical-centered environment, the methodology carried with it a significant potential training effect, and the placebo group had higher baseline values than the treatment group. In another warning time study (Zinner et al., 2006) on 445 OAB patients, darifenacin treatment (15 mg) resulted in numeric increases in warning time; however, these were not significant compared with placebo.

Further studies have demonstrated that darifenacin treatment is associated with clinically relevant improvements in health-related quality of life (QoL) in patients with OAB (Abrams et al., 2008), and such improvements were sustained as shown in a 2-year extension study (Dwyer et al., 2008). It was shown that neither the positive effects on micturition variables nor those on health-related QoL produced by darifenacin (7.5 and 15 mg) were further enhanced by a behavior modification program including timed voiding, dietary modifications, and Kegel exercises (Chancellor et al., 2008b).

Because darifenacin is a substrate for the P-glycoprotein drug efflux transporter (Chancellor et al., 2012; Miller et al., 2011), which is present in both the blood-brain and the blood-ocular barriers, several clinical studies have been devoted to investigate possible effects of darifenacin on cognition. Compared with placebo, no effect of darifenacin (3.75 to 15 mg daily) could be demonstrated in healthy volunteers 19 to 44 years of age, healthy patients 60 years of age or older, or volunteers 65 years of age or older (Chancellor et al., 2012; Kay and Ebinger 2008; Kay and Wesnes, 2005; Kay et al., 2006; Lipton et al., 2005).

To study whether darifenacin had any effect on QT and QTc intervals, Serra et al. (2005) performed a 7-day, randomized, parallel-group study (n = 188) in healthy volunteers receiving once-daily darifenacin at steady-state therapeutic (15 mg) and supratherapeutic (75 mg) doses alongside controls receiving placebo or moxifloxacin (positive control, 400 mg) once daily. No significant increase in Fridericia's corrected QT interval (QTcF) could be demonstrated compared with placebo. Mean changes from baseline at pharmacokinetic Tmax versus placebo were −0.4 and −2.2 msec in the darifenacin 15-mg and 75-mg groups, respectively, compared with +11.6 msec in the moxifloxacin group ($P < .01$). The conclusion was that darifenacin does not prolong the QT or QTc interval.

Darifenacin 15 mg/day given to healthy volunteers did not significantly change HR compared with placebo (Olshansky et al., 2008). The impact of darifenacin on constipation has been assessed in an analysis of the phase III, IIIb, and IV darifenacin published trials (Tack et al., 2012). The pooled phase III data suggested 14.8% (50/337) of patients on darifenacin 7.5 mg/day and 21.3% (71/334) on 15 mg/day experienced constipation. Only 0.6% and 1.2% of patients taking darifenacin 7.5 mg/day and 15 mg/day, respectively, stopped treatment as a result of constipation. Furthermore, 3.3% [11/337] and 6.6% [22/334] in the darifenacin 7.5 mg/day and 15 mg/day groups required concomitant laxative medications. At the end of a long-term study (2 years), the incidence of constipation was 20.9% (150/716), and 5.6% (40/716) of patients initiated use of fiber supplements, stool softeners, or laxatives (Tack et al. 2012).

Assessment.

Darifenacin has a well-documented beneficial effect in OAB and DO (see Table 120.3), and tolerability and safety seem acceptable.

Fesoterodine Fumarate.

Fesoterodine functions as an orally active prodrug that is converted to the active metabolite 5-HMT by nonspecific esterases (Malhotra et al., 2009b; Michel, 2008). This compound, which is chemically identical to the 5-hydroxy metabolite of tolterodine, is a **non–subtype selective muscarinic-receptor antagonist** (Ney et al., 2008)**. All of the effects of fesoterodine in humans are thought to be mediated via 5-HMT,** because the parent compound remains undetectable after oral administration. 5-HMT is metabolized in the liver, but a significant part of 5-HMT is excreted renally without additional metabolism. Because the renal clearance of 5-HMT is about 250 mL/min, with more than 15% of the administered fesoterodine dose excreted as unchanged 5-HMT, this raises the possibility that 5-HMT also could work from the luminal side of the bladder (Michel, 2008). The bioavailability of fesoterodine, averaging 52%, was independent of food intake, and the drug may be taken with or without a meal (Malhotra et al., 2009c). Peak plasma concentration of 5-HMT is reached at 5 hours after oral administration, and the agent has a half-life of 7 to 9 hours (Malhotra et al., 2008). The suggested starting dose, 4 mg/day, can be used in patients with moderately impaired renal or hepatic function because of the combination of renal excretion and hepatic metabolism of 5-HMT (de Mey et al., 2011; Malhotra et al., 2009a).

The clinical efficacy and tolerability of fesoterodine have been documented in several RCTs (Chapple et al., 2007b; Dell'Utri et al., 2012; Dmochowski et al., 2010c; Herschorn et al., 2010; Kaplan et al., 2011; Nitti et al., 2007, 2010). In a multicenter, double-blind, double-dummy RCT with tolterodine ER, 1132 patients were enrolled and received treatment (Chapple et al., 2007b). The trial showed that both the 4- and 8-mg doses of fesoterodine were effective in improving symptoms of OAB, with the 8-mg dose having a greater effect at the expense of a higher rate of dry mouth. There appeared to be little difference between fesoterodine 4 mg and tolterodine ER. Only one patient from the fesoterodine 8-mg group and one patient from the tolterodine ER group withdrew from the study because of dry mouth. The dose-response relationship was confirmed in another study that pooled data from two phase III RCTs (Khullar et al., 2008). Fesoterodine 8 mg performed better than the 4-mg dose in improving urgency and urge UI as recorded by 3-day bladder diary, offering the possibility of dose titration.

A head-to-head placebo-controlled trial compared fesoterodine 8 mg with tolterodine ER 4 mg and placebo (Herschorn et al., 2010). The study randomized 1590 patients to assess the primary outcome of reduced urgency incontinence episodes at 12 weeks. Fesoterodine produced statistically significant improvements in urgency incontinence episodes, complete dry rates (64.0% vs. 57.2%, $P = .015$), and MVV per void (+32.9 mL vs. +23.5 mL, $P = .005$) and in patients' assessments of bladder-related problems as measured by the OAB questionnaire (except sleep domain), Patient Perception of Bladder Condition (PPBC; 40% vs. 33% with >2-point improvement, $P < .001$), and Urgency Perception Scale (46% vs. 40% with improvement, $P = .014$) compared with tolterodine. The clinical significance of these statistically significant findings is questionable because there was no difference between agents with respect to number of micturitions, urgency episodes, and frequency-urgency sum per 24 hours. The improved efficacy of fesoterodine came at the cost of greater dry mouth (27.8% vs. 16.4%), headache (5.6% vs. 3.4%), constipation (5.4% vs. 4.1%), and withdrawal rates (6% vs. 4%). Nonetheless, this first head-to-head trial comparing two drugs in class supports the use of fesoterodine 8 mg for additional benefit over tolterodine ER 4 mg.

Wyndaele et al. (2009) reported the first flexible-dose open-label fesoterodine trial, which was conducted at 80 different centers worldwide and included 516 participants (men and women) older than 18 years of age who self-reported OAB symptoms for at least 3 months before screening and had been treated with either tolterodine or tolterodine ER within 2 years without symptom improvement. Approximately 50% opted for dose escalation to 8 mg at week 4. Significant improvements from baseline to week 12 were observed in micturitions, urgency urinary incontinence (UUI) episodes, micturition-related urgency episodes, and severe micturition-related urgency episodes per 24 hours. Significant improvements from baseline were observed in QoL parameters. Dry mouth (23%) and constipation (5%) were the most common adverse events; no safety issues were identified.

Kaplan et al. (2011) performed the largest double-blind, double-dummy, flexible-dose fesoterodine RCT, which was conducted at 210 different centers with 2417 patients enrolled. All patients were healthy, older than 18 years of age, and self-reported OAB symptoms for at least 3 months. The 960 patients who received fesoterodine 8 mg showed significantly greater mean improvements at week 12 in most efficacy parameters (diary variables)—UUI and urgency episodes, micturition frequency, and MVV—than those receiving either tolterodine ER 4 mg or placebo. No statistically significant changes were shown in reduction of nocturnal micturitions compared with the tolterodine group, whereas when comparing the mean changes in nighttime micturition with the placebo group a significant difference was found. This phase III study confirmed the superiority of fesoterodine 8 mg over tolterodine ER 4 mg for improving UUI and urgency episodes and 24-hour micturitions but not for MVV and nocturia. In another RCT of flexible-dose fesoterodine, Dmochowski et al. (2010c) reported statistically significant improvements at week 12 in the mean number of micturitions per 24 hours and in both UUI and urgency episodes. Between groups, the difference in nocturnal micturition was not statistically significant.

A subsequent pooled analysis of two phase III trials confirmed superiority of fesoterodine 8 mg to tolterodine ER 4 mg (Ginsberg et al., 2013). In women, fesoterodine 8 mg was superior to tolterodine 4 mg at 12 weeks in UUI, urgency, micturition episodes, diary dry rates, Patient Perception of Bladder Condition (PPBC), Urge Perception Score (UPS), and Overactive Bladder Questionnaire (OAB-q) scores. In men, superiority with fesoterodine 8 mg was only demonstrated for severe urgency and the symptom bother domain of the OAB-q. In women, dry mouth rates were 29%, 15%, and 6%; constipation rates were 5%, 4%, and 2%; and urinary retention rates were <1%, <1%, and 0% for fesoterodine 8 mg, tolterodine ER 4 mg, and placebo, respectively. In men, dry mouth rates were 21%, 13%, and 5%; constipation rates were 5%, 3%, and 1%; and urinary retention rates were 2%, <1%, and 2% for fesoterodine 8 mg, tolterodine ER 4 mg and placebo, respectively (Ginsberg et al., 2013).

Kaplan et al. (2014) assessed fesoterodine 8 mg and placebo in patients who had not responded to tolterodine ER 4 mg (<50% reduction in UUI). At week 12, UUI and urgency episodes were significantly better in the fesoterodine group, but micturition episodes and diary dry rates were statistically no different compared with placebo. Patients with greater than 50% and greater than 70%

UUI episodes showed improvement in the fesoterodine 8 mg group at 8 weeks. Furthermore, at 12 weeks, improvements in favor of fesoterodine compared with placebo were seen in PPBC, UPS, and OAB-q scores. Dry mouth and constipation were seen in 16.6% and 3.9% in the fesoterodine group and 4% and 1.3% in the placebo group, respectively (Kaplan et al., 2014).

Little is known on the impact of antimuscarinics on nocturnal urgency. Weiss et al. (2013) explored this is a multicenter randomized, double-blind, placebo-controlled 12-week flexible dosing trial in the United States. In the fesoterodine group, 61% were escalated at the clinicians' discretion to the 8-mg dose. Nocturnal urgency episodes (–1.28 vs. –1.07), nocturnal micturition episodes, and nocturnal frequency-urgency sum (urgency sensations were rated on a 1 to 5 scale), were significantly better in the fesoterodine group. Interestingly, UUI per 24 hours was not statistically different between fesoterodine and placebo in this trial, and the authors acknowledge there is no minimally important difference in nocturnal urgency episodes to ascertain clinical significance definitively. However, in an Asian post-hoc analysis of a double-blind placebo-controlled trial of fesoterodine 4 mg and 8 mg involving 555 patients, fesoterodine was not statistically better than placebo in reducing nocturnal micturition episodes at 12 weeks (Yokoyama et al., 2014). If patients with a nocturnal polyuris index of >33% were excluded, fesoterodine 8 mg was statistically better than placebo in reducing nocturnal micturition episodes. Undisturbed sleep increased in both fesoterodine arms (4 mg, 80 minutes; 8 mg, 74 minutes) but was only statistically significant in the 4-mg dose compared with placebo (54 minutes). Significant improvements in the sleep/energy domain of the King's Health Questionnaire (KHQ) was seen in both fesoterodine groups compared with placebo.

Nitti et al. (2010) determined whether the presence of DO in patients with OAB and UUI was a predictor of the response to treatment with fesoterodine in a phase II randomized, multicenter, placebo-controlled trial. They concluded that regardless of the presence of DO, the response to fesoterodine treatment was dose-proportional and associated with significant improvements in OAB symptoms, indicating that **the response to OAB pharmacotherapy in patients with UUI was independent of the urodynamic diagnosis of DO.**

Kelleher et al. (2008) evaluated the effect of fesoterodine on health-related QoL in patients with OAB syndrome. Pooled data from two randomized placebo-controlled phase III studies were analyzed (Chapple et al., 2007b; Nitti et al., 2007). Eligible patients were randomized to placebo or fesoterodine 4 or 8 mg for 12 weeks; one trial also included tolterodine ER 4 mg. By the end of treatment, all active-treatment groups had significantly improved health-related QoL compared with those on placebo. In a post-hoc analysis of data pooled from these studies, significant improvements in all King's Health Questionnaire (KHQ) domains, International Consultation on Incontinence Questionnaire Urinary Incontinence Short Form (ICIQ-UI-SF) scores, and bladder-related problems were observed at 12 and 24 months compared with open-label baseline (Kelleher et al., 2012). The authors concluded that treatment satisfaction was high throughout the open-label treatment regardless of gender and age.

A large postmarketing study from Korea has confirmed the efficacy of fesoterodine in OAB (Kim et al., 2016). The mean duration of symptoms was 165 days, but, interestingly, 63% had symptom duration of less than 1 week. Of the patients included, 92.7% (2879/3107), 76.8% (2387/3107), and 37.5% (1164/3107) reported having symptoms of urinary frequency, urgency, and UUI, respectively, and mean fesoterodine treatment duration was 83.2 ± 75.3 days. Frequency, urgency, and UUI per 24 hours declined from 12.1 to 8.0, 3.7 to 1.3, and 1.1 to 0.3, respectively (all $P < 0.001$). Utilizing the PPBC questionnaire, their bladder condition caused some very minor problems (43.0%, 1265/2939) or no problems at all (22.2%, 651/2939). Adverse events were reported in 8.2%, with dry mouth in 5.4% and constipation in 1.5% (Kim et al. 2016).

Malhotra et al. (2010) performed a thorough QT study to investigate the effects of fesoterodine on cardiac repolarization in a parallel-group study. Subjects were randomly assigned to receive double-blind fesoterodine 4 mg, fesoterodine 8 mg, or placebo or open-label moxifloxacin 400 mg (positive control) for 3 days. Electrocardiograms (ECGs) were obtained on days 1 (baseline) and 3. The primary analysis was of the time-averaged changes from baseline for QTcF on day 3. Among 261 subjects randomized to fesoterodine 4 mg ($n = 64$), fesoterodine 28 mg ($n = 68$), placebo ($n = 65$), or moxifloxacin 400 mg ($n = 64$), 256 completed the trial. The results indicated that fesoterodine is not associated with QTc prolongation or other ECG abnormalities at either therapeutic or supratherapeutic doses.

Assessment.

Fesoterodine has a well-documented beneficial effect in OAB (see Table 120.3), and the adverse event profile seems acceptable.

Imidafenacin.

Imidafenacin (KRP-197/ONO-8025, 4-[2-methyl-1H-imidazol-1-yl]-2,2-diphenylbutanamide) is **an antagonist for the muscarinic ACh receptor with higher affinities for M_3 and M_1 receptors than for the M_2 receptor.** Metabolites of imidafenacin (M-2, M-4, and M-9) had low affinities for muscarinic ACh receptor subtypes (Kobayashi et al., 2007). The drug blocks prejunctional and postjunctional muscarinic receptors and was shown to block both detrusor contractions and ACh release (Murakami et al., 2003). The receptor-binding affinity of imidafenacin in vitro was found to be significantly lower in the bladder than in the submaxillary gland or colon (Yamada et al., 2011), and in rats orally administered imidafenacin distributes predominantly to the bladder and exerts more selective and longer-lasting effect there than on other tissues. Whether this can be translated to the human situation has to be established before claims of clinical bladder selectivity can be made.

Imidafenacin is well absorbed from the gastrointestinal tract, and its absolute bioavailability in humans is 57.8% (Ohmori et al., 2007; Ohno et al., 2008). It is rapidly absorbed, with maximum plasma concentration occurring 1 to 3 hours after oral administration (Ohno et al., 2008). Metabolites in the plasma are produced mainly by first-pass effects. The major enzymes responsible for the metabolism of the drug are CYP3A4 and UGT1A4. The oxidative metabolism is reduced by concomitant administration of CYP3A4 inhibitors. In contrast, imidafenacin and its metabolites have no inhibitory effect on the CYP-mediated metabolism of concomitant drugs (Kanayama et al., 2007).

Kitagawa et al. (2011) reported that the subjective efficacy of imidafenacin was observed from 3 days after the commencement of administration and that the mean total Overactive Bladder Symptom Score (OABSS) decreased gradually during 2 weeks after administration.

A randomized, double-blind, placebo-controlled phase II dose-finding study in Japanese OAB patients was performed to evaluate the efficacy, safety and tolerability, and dose-response relationship of imidafenacin (Homma et al., 2008). Overall, 401 patients were enrolled and randomized for treatment with 0.1 mg of imidafenacin per day (99 patients), 0.2 mg of imidafenacin per day (100), 0.5 mg of imidafenacin per day (101), or placebo (101). After 12 weeks of treatment, the number of incontinence episodes was reduced in a dose-dependent manner, and a significant difference between the imidafenacin treatment and the placebo groups was observed ($P < .0001$). Compared with placebo, imidafenacin caused significant reductions in urgency incontinence, voiding frequency, and urinary urgency and a significant increase in the urine volume voided per micturition. Imidafenacin was also well tolerated. The incidence of dry mouth in the imidafenacin groups increased in a dose-dependent manner. Even though the percentage of patients receiving 0.5 mg/day who discontinued treatment because of dry mouth was high (8.9%), the percentages in the 0.1 mg/day and 0.2 mg/day groups (1.0% and 0.0%, respectively) were comparable with that in the placebo group (0.0%).

Homma et al. (2009) conducted a randomized, double-blind, placebo- and propiverine-controlled trial of 781 Japanese patients with OAB symptoms. Patients were randomized to imidafenacin (324), propiverine (310), or a placebo (147). After 12 weeks of treatment, a significantly larger reduction in the mean number of incontinence episodes was observed in the imidafenacin group than in the placebo group ($P < .0001$). The noninferiority of imidafenacin compared with propiverine was confirmed for the reduction in UI episodes ($P = .0014$; noninferiority margin, 14.5%). Imidafenacin was well tolerated. The incidence of adverse events with imidafenacin was significantly lower than with propiverine ($P = .0101$). Dry mouth, the most common adverse event, was significantly more common in the propiverine group than in the imidafenacin group. There were no significant increases in either the imidafenacin or the placebo group in the mean QTc interval, whereas there was a significant increase in the mean QTc interval in the propiverine group ($P < .0001$). However, clinical arrhythmia and clinical arrhythmic events were not seen in any of the treatment groups.

The long-term safety, tolerability, and efficacy of imidafenacin were studied in Japanese OAB patients (Homma et al., 2008), of whom 478 received treatment and 376 completed a 52-week program. Imidafenacin was well tolerated, the most common adverse event being dry mouth (40.2% of the patients). Long-term treatment did not produce an increase in the frequency of adverse events compared with short-term treatment. A significant efficacy of the drug was observed from week 4 to week 52. After 52 weeks, imidafenacin had produced mean changes from baseline in the number of incontinence episodes (−83.51%), urgency incontinence episodes (−84.21%), voiding frequency (−2.35 micturitions per day), urgency episodes (−70.53%), and volume voided per micturition (28.99 mL). There were also significant reductions from baseline in all domains of the KHQ. Imidafenacin had no significant effects on the corrected QT interval, vital signs, results from laboratory tests, or postvoid residual (PVR) volume.

Zaitsu et al. (2011) conducted a 52-week prospective, open, randomized, comparative study to evaluate the efficacy and tolerability of imidafenacin (0.2 mg/day) and solifenacin (5 mg/day) in a total of 41 Japanese patients with untreated OAB. They were randomly assigned to imidafenacin and solifenacin groups. There were no differences in OAB and KHQ scores between the two groups, but the severity and incidence of adverse events caused by the drugs showed increased differences between the groups with time. The severity of dry mouth and the incidence of constipation were significantly lower in the imidafenacin group ($P = .0092$ and $P = .0013$, respectively). An important limitation of this study is the low number of patients. Only 25 patients (17 male, 8 female) were available for long-term analysis.

Yokoyama et al. (2013) reported similar results in their comparative long-term study with equivalent efficacy and better tolerability for imidafenacin compared with solifenacin, but high discontinuation rates in both arms at study end.

Two small open-label studies and a post-hoc analysis of a large multicenter RCT of imidafenacin have suggested benefits on noctura and/or nocturnal polyuria (Kadekawa et al.,. 2012; Wada et al., 2012; Yokoyama et al., 2013). Wada et al. (2012) reported improvements in OAB symptoms, Pittsburgh Sleep Quality Index scores, nocturia episodes, and nocturnal polyuria in patients older than 75 years of age with imidafenacin 0.1 mg twice daily. Patients whose main complaint was nocturia were treated with 0.1 mg daily and after 4 weeks were allowed a dose escalation to 0.2 mg daily if required. This group showed significant improvements with regard to nocturia and other OAB parameters, OABSS, and International Prostate Symptom Score (IPSS)-QoL Index score (Kadekawa et al., 2012). A stratified analysis of a large RCT showed that in 46 patients with nocturia and nocturnal polyuria (>33% urine production at night), imidafenacin 0.1 mg twice daily after 12 weeks of treatment significantly reduced nighttime micturition and nocturnal percentage of 24-hour production, and the interval to the first nighttime void was significantly longer compared with placebo (Yokoyama et al., 2013).

A multicenter noninferiority phase IV trial of imidafenacin 0.1 mg twice daily versus fesoterdine 4 mg was conducted in Korea (Lee et al., 2013). No significant differences were observed between the two treatments for OAB symptoms of KHQ scores. Dry mouth rates were 39.4% and 37.3% in the imidafenacin and fesoterodine groups, respectively, and no statistical differences were shown for adverse events, blood pressure, pulse, or residual volume between the groups. In another postmarketing surveillance study, imidafenacin was shown to be safe, with dry rates of 8.5% and no significant deterioration in

MMSE at 48 weeks, with an acceptable mild cognitive impairment conversion to dementia rate (3.6%) (Sakakibara et al., 2014).

Assessment.

Imidafenacin seems to be effective and to have an acceptable tolerability (see Table 120.3).

Propantheline Bromide.

Propantheline is a quaternary ammonium compound, nonselective for muscarinic receptor subtypes, that has a low (5% to 10%) and individually varying biologic availability. It is metabolized (metabolites inactive) and has a short half-life (less than 2 hours) (Beermann et al., 1972). It is usually given in a dose of 15 to 30 mg four times daily, but to obtain an optimal effect, individual titration of the dose is necessary, and often higher doses are required. Using this approach in 26 patients with DO contractions, Blaivas et al. (1980) in an open study obtained a complete clinical response in all patients but one, who did not tolerate more than propantheline 15 mg four times daily. The range of doses varied from 7.5 to 60 mg four times daily. In contrast, Thüroff et al. (1991), comparing the effects of oxybutynin 5 mg three times daily, propantheline 15 mg three times daily, and placebo in a randomized, double-blind, multicenter trial on the treatment of frequency, urgency, and incontinence related to DO (154 patients) found no differences between the placebo and propantheline groups. In another randomized comparative trial with crossover design (23 women with idiopathic detrusor overactivity [IDO]) and with dose titration, Holmes et al. (1989) found no differences in efficacy between oxybutynin and propantheline. Six controlled randomized trials reviewed by Thüroff et al. (1998) confirmed a positive but varying response to the drug.

Assessment.

Although the effect of propantheline on OAB and DO has not been well documented in controlled trials satisfying the standards of today, it can be considered effective and may be clinically useful in individually titrated doses (see Table 120.3). No new studies on the use of this drug for treatment of OAB and DO seem to have been performed during the past decade.

Solifenacin Succinate.

Solifenacin succinate (YM905) is a tertiary amine that is well absorbed from

the gastrointestinal tract (absolute bioavailability 90%). The mean terminal half-life is 45 to 68 hours (Kuipers et al., 2002; Smulders et al., 2002, 2004). **It undergoes significant hepatic metabolism** involving the cytochrome P450 enzyme system (CYP3A4). In patients who received a single oral dose of 10 mg solifenacin on day 7 of a 20-day regimen of ketoconazole administration (200 mg), Cmax and AUC0-inf were increased by only approximately 40% and 56%, respectively (Swart et al., 2006). **Solifenacin has a modest selectivity for M_3 over M_2 (and M_1) receptors** (Abrams and Andersson, 2007). Supporting an effect of solifenacin on sensory function, 15 women with DO receiving 10 mg of the drug per day showed an increase in the area under the bladder-volume sensation curve (Lowenstein et al., 2012). Solifenacin also increased maximum bladder capacity, a finding in agreement with other studies (Hsiao et al., 2011; Tanaka et al., 2010).

Two large-scale phase II trials with parallel designs, including men and women, were performed (Chapple et al., 2004a; Smith et al., 2002). The first dose-ranging study evaluated solifenacin 2.5 mg, 5 mg, 10 mg, and 20 mg and tolterodine (2 mg twice daily) in a multinational placebo-controlled study of 225 patients with urodynamically confirmed DO (Chapple et al., 2004a). Patients received treatment for 4 weeks followed by 2 weeks of follow-up. Inclusion criteria for this and subsequent phase III studies of patients with OAB included at least eight micturitions per 24 hours and either one episode of incontinence or one episode of urgency daily as recorded in 3-day micturition diaries. Micturition frequency, the primary efficacy variable, was statistically significantly reduced in patients taking solifenacin 5 mg (−2.21), 10 mg (−2.47), and 20 mg (−2.75), but not in patients receiving placebo (−1.03) or tolterodine (−1.79). This effect was rapid, with most of the effect observed at the earliest assessment visit, 2 weeks after treatment initiation. In addition, there were numerically greater reductions in episodes of urgency and incontinence when compared with placebo. Study discontinuations caused by adverse events were similar across treatment groups, albeit highest in the 20-mg solifenacin group. Because the 5-mg and 10-mg doses caused lower rates of dry mouth than tolterodine and had superior efficacy outcomes relative to placebo, these dosage strengths were selected for further evaluation in large-scale phase III studies.

The second dose-ranging study of solifenacin 2.5 mg to 20 mg was carried out in the United States (Smith et al., 2002). This trial included 261 evaluable men and women receiving solifenacin or placebo for 4 weeks followed by a 2-week follow-up period. Micturition frequency was statistically significantly reduced relative to placebo in patients receiving 10 mg and 20 mg of solifenacin. The number of micturitions per 24 hours showed reductions by day 7 and continued to decrease through day 28; day 7 was the earliest time point tested in solifenacin trials, and these findings demonstrated efficacy as early as 1 week. The 5-mg, 10-mg, and 20-mg dosage groups experienced statistically significant increases in volume voided; the 10-mg solifenacin dose was associated with statistically significant reductions in episodes of incontinence.

In one of the early RCTs, 1077 patients were randomized to 5-mg solifenacin, 10-mg solifenacin, tolterodine (2 mg twice daily), or placebo (Chapple et al., 2004b). It should be noted that this study was powered only to compare active treatments with placebo. Compared with placebo (−8%), mean micturitions per 24 hours were significantly reduced with solifenacin 10 mg (−20%), solifenacin 5 mg (−17%), and tolterodine 2 mg twice daily (−15%). Solifenacin was well tolerated, with few patients discontinuing treatment. Incidences of dry mouth were 4.9% with placebo, 14.0% with solifenacin 5 mg, 21.3% with solifenacin 10 mg, and 18.6% with tolterodine 2 mg twice daily.

Cardozo et al. (2004b) randomized 911 patients to 12-week once-daily treatment with solifenacin 5 mg, solifenacin 10 mg, or placebo. The primary efficacy variable was change from baseline to study end point in mean number of micturitions per 24 hours. Secondary efficacy variables included changes from baseline in mean number of urgency, nocturia, and incontinence episodes per 24 hours, and MVV per micturition. Compared with changes obtained with placebo (−1.6), the number of micturitions per 24 hours was statistically significantly decreased with solifenacin 5 mg (−2.37) and 10 mg (−2.81). A statistically significant decrease was observed in the number of all incontinence episodes with both solifenacin doses (5 mg, −1.63, 61%; 10 mg, −1.57, 52%), but not with placebo (−1.25, 28%). Of patients reporting incontinence at baseline, 50% achieved continence after treatment with solifenacin (based on a 3-day micturition diary, placebo responses not given). Episodes of nocturia were statistically significantly decreased in patients treated with solifenacin 10 mg versus placebo. Episodes of urgency and MVV per micturition were statistically significantly reduced with solifenacin 5 mg and 10 mg. Treatment with solifenacin was well tolerated. Dry mouth, mostly mild in severity, was reported in 7.7% of patients receiving solifenacin 5 mg and 23% receiving solifenacin 10 mg (vs. 2.3% with placebo). A 40-week follow-up of these studies demonstrated that the favorable profile, both in terms of efficacy and tolerability, was maintained over the study period (Cardozo et al., 2004b; Chapple et al., 2004b;

Haab et al., 2005).

The STAR trial (Chapple et al., 2005c, 2007c) was a prospective, double-blind, double-dummy, two-arm, parallel-group, 12-week study conducted to compare the efficacy and safety of solifenacin 5 or 10 mg and tolterodine extended release (TOLT-ER) 4 mg once daily in OAB patients. The primary effect variable was micturition frequency. After 4 weeks of treatment, patients had the option to request a dose increase, but were dummied throughout because approved product labeling allowed an increase only for those on solifenacin. The results showed that solifenacin, with a flexible dosing regimen, was noninferior to tolterodine with regard to the primary effect variable, micturition frequency. However, solifenacin showed significant greater efficacy to tolterodine in decreasing urgency episodes (−2.85 vs. −2.42), incontinence (−1.60 vs. −.83), urgency incontinence (−1.42 vs. −0.83), and pad use (−1.72 vs. −1.19). More solifenacin-treated patients became continent by study end point (59% vs. 49%) and reported improvements in perception of bladder condition (−1.51 vs. −1.33) assessments. However, this was accompanied by an adverse event incidence that was greater with solifenacin than with tolterodine. Dry mouth and constipation (mild, moderate, or severe) were the most common (solifenacin, 30 [6.4%]; tolterodine, 23 [2.5%]). The majority of side effects were mild to moderate in nature, and discontinuations were comparable and low (5.9% and 7.3%) in both groups.

Luo et al. (2012) performed a systematic review and meta-analysis of solifenacin RCTs and provided a comprehensive assessment regarding the efficacy and safety of the drug. Their results, which largely confirmed what could be deduced from previously published information, indicated that solifenacin significantly decreased the number of urgency episodes per 24 hours, micturitions per 24 hours, incontinence episodes per 24 hours, nighttime micturitions per 24 hours, and UUI episodes per 24 hours and improved volume voided per micturition compared with placebo or the tolterodine treatment.

A number of studies and reviews have further documented the effects of solifenacin (Cardozo et al., 2006; Chapple et al., 2006a, 2007c; Maniscalco et al., 2006; see also Chapple et al., 2008b; Luo et al., 2012; Novara et al., 2008; Serels et al., 2010; Toglia et al., 2009; Vardy et al., 2009), including in men with OAB without BOO (Kaplan et al., 2010). In a pooled analysis of four RCTs, Abrams and Swift demonstrated positive effects on urgency, frequency, and nocturia symptoms in OAB dry patients (Abrams and Swift, 2005). In an analysis of four phase III clinical trials, Brubaker and FitzGerald confirmed a significant effect of solifenacin 5 and 10 mg on nocturia in patients with OAB (reductions of nocturia episodes with 5 mg, −0.6, $P < .025$; with 10 mg, −0.6, $P < .001$; vs. placebo, −0,4) but without nocturnal polyuria (NP) (Brubaker and FitzGerald, 2007). Other studies have reported a positive impact on nocturia and sleep quality in patients with OAB treated with solifenacin (Takao et al., 2011; Yokoyama et al., 2011). Kelleher et al. (2006) and Staskin and Te (2006) presented data showing efficacy in patients with mixed incontinence.

A pooled analysis of four studies confirmed the efficacy and tolerability of solifenacin 5 mg and 10 mg in elderly (65 years or older) patients and also showed a high level of persistence in a 40-week extension trial (Wagg et al., 2006). Post hoc analysis of two 12-week, open-label, flexible-dosage studies on 2645 patients older than 65 years of age with OAB revealed that solifenacin was associated with improvements in measures assessing patients' perception of their bladder problems, symptom bothersomeness, and aspects of health-related QoL (Capo' et al., 2011). Solifenacin was equally well tolerated in younger (<65 years) and older (>65 years) patients (Herschorn et al., 2011b). An exploratory pilot study with single doses of solifenacin 10 mg administered to 12 elderly volunteers suggested no clear propensity to impair cognitive functions (Wesnes et al., 2009).

Several studies have documented improvement of QoL with solifenacin treatment (Garely et al., 2006; Kelleher et al., 2005). In 30 patients with multiple sclerosis, van Rey and Heesakkers (2011) improved OAB symptoms and neurogenic disease-specific QoL measures.

Information on solifenacin treatment in children is scarce. A chart review of 138 children with therapy-resistant OAB, treated with solifenacin, showed increased mean voided volume and improved continence (Hoebeke et al., 2009). An open-label study utilizing solifenacin doses 1.25 mg to 10 mg in children with refractory incontinence was reported (Nadeau et al., 2014). In total, 112 girls and 132 boys were included (191 had IDO, and 53 had NDO), with mean age of 9.2 years at the start of treatment. Significant improvements were seen in urodynamic parameters, PPBC, and UI episodes, with the dry rate being 36%. Treatment outcomes were more successful for IDO than NDO. The majority of patients reported no side effects ($n = 175$).

The SONIC trial assessed efficacy and tolerability of solifenacin in patients with multiple sclerosis (MS) and SCI in a prospective randomized phase IIIb/IV parallel group study (Amarenco et al., 2017). Approximately one-fourth of the patients were taking muscle relaxants to help with spasticity. Patients were randomized to solifenacin 5 mg, solifenacin 10 mg, oxybutynin 5 mg three times daily, or placebo for 4 weeks after a placebo run-in. The primary analysis was solifenacin 10 mg vs placebo. The majority of MS patients were female, and the majority of SCI patients were male. The primary end point of maximum cystometric capacity was significantly increased with solifenacin 10 mg (134 mL) compared with placebo (5 mL). Furthermore, significant improvements were also observed with regard to bladder volume at first contraction and at first leak and detrusor pressure at first leak. PPBC and I-QoL subscales significantly improved in favor of solifeancin 10 mg compared with placebo. Significant improvements were also seen for oxybutynin compared with placebo, but the trial was not designed to compare outcomes of the different active treatments (Amarenco et al. 2017). The overall incidence of adverse events were low, and dry mouth rates were 2.3%, 4.2%, 7.8%, and 17% for placebo, solifenacin 5 mg, solifenacin 10 mg and oxybutynin 5 mg three times daily, respectively.

A noninterventional observational study in men alone ($n = 799$) was conducted in multiple centers in Germany in a real-life practice setting (Burger et al. 2014). In this 12-week study, the majority were taking solifenacin 5 mg at study end (71%), and only 1.9% discontinued the treatment. Significant improvement in OAB symptoms were observed. In a subgroup of men with mild to moderate dementia, Mini Mental State Examination (MMSE) scores did not change significantly over the 12 weeks. Unusually dry mouth was only reported in 1.1%, and mean PVR did not change. In 80% PVR did not change, and in only 2.2% was the change greater than or equal to 50 mL. No retention of urine was observed (Burger et al., 2014).

Serati et al. assessed the use of solifenacin 5 mg in patients with de novo OAB symptoms after an obturator midurethral synthetic sling and compared this to a group who was stress-incontinence treatment naïve (Serati et al., 2014). Women with a pre-existing diagnosis of DO or who had OAB symptoms were excluded as were patients with significant voiding dysfunction or persistent stress incontinence. At 3-month follow-up, interestingly, the reduction in all OAB symptoms, Patient Global Impression of Improvement (PGI-I), and OAB-q SF scores were significantly better in the stress-incontinent treatment naïve group compared with the de novo OAB group.

Jiang et al. (2016) studied the efficacy and safety of solifenacin succinate versus solifenacin succinate with local estrogen for the treatment of overactive bladder in 104 postmenopausal women randomized to receive either solifenacin 5 mg daily plus promestriene vaginal capsules or solifenacin alone. The primary outcome measure was change from baseline to end of treatment in the mean number of voids per 24 hours. QoL was assessed using IPSS and OAB symptoms score questionnaires. The median decreases in number of voids in 24 hours in the two groups were 5.4 and 4.3, respectively, which was not statistically different. The median decrease in urgency episodes was 2.0 and 2.5, respectively. In addition, the QoL scores significantly changed in both groups (both <0.05). The authors concluded that solifenacin with or without local estrogen was effective and safe for overactive bladder treatment in postmenopausal women. The addition of local estrogen improved subjective feelings and QoL (Jiang et al., 2016).

Michel et al. (2008) studied cardiovascular safety and overall tolerability of solifenacin in routine clinical use in a 12-week, open-label, postmarketing surveillance study. They concluded that "in real-life conditions, i.e., with inclusion of large numbers of patients with cardiovascular co-morbidities and taking comedications, therapeutically effective doses of solifenacin did not increase heart rate or blood pressure."

In female volunteers 19 to 79 years of age, the effect of 10 mg and 30 mg of solifenacin on QT interval was evaluated at the time of peak solifenacin plasma concentration in a multidose, randomized, double-blind, placebo- and positive-controlled (moxifloxacin 400 mg) trial (Product monograph, Vesicare). The QT interval prolonging effect appeared greater for the 30 mg (8 msec, 4, 13: 90% CI) compared with the 10 mg (2 msec, –3, 6) dose of solifenacin. Although the effect of the highest solifenacin dose (three times the maximum therapeutic dose) studied did not appear as large as that of the positive control moxifloxacin at its therapeutic dose, the confidence intervals overlapped. This study was not designed to draw direct statistical conclusions between the drugs or the dose levels.

Assessment.

Solifenacin has a well-documented beneficial effect in OAB and DO (see Table 120.3), and the adverse-event profile seems acceptable.

Tolterodine Tartrate.

Tolterodine is a tertiary amine that is rapidly absorbed and extensively metabolized by the cytochrome P450 system (CYP2D6). The major active 5-hydroxymethyl metabolite (5-HMT) has a similar pharmacologic profile as the mother compound (Nilvebrant et al., 1997b) **and significantly contributes**

to the therapeutic effect of tolterodine (Brynne et al., 1997, 1998). Both tolterodine and 5-HMT have a plasma half-life of 2 to 3 hours, but the effects on the bladder seem to be longer lasting than could be expected from the pharmacokinetic data. Urinary excretion of tolterodine accounted for less than 1% to 2.4% of the dose; 5% to 14% of 5-HMT is eliminated in the urine (Brynne et al., 1997). Whether or not the total antimuscarinic activity of unchanged tolterodine and 5-HMT excreted in urine is sufficient to exert any effect on the mucosal signaling mechanisms has not been established. However, the preliminary studies by Kim et al. (2006) and Chuang et al. (2008) do not support such an effect.

The relatively low lipophilicity of tolterodine and even lesser one of 5-HMT imply limited propensity to penetrate into the CNS, which may explain a low incidence of cognitive side effects (Clemett and Jarvis, 2001; Hills et al., 1998; Salvatore et al., 2008). However, tolterodine may disturb sleep in subjects who are unable to form the even less lipophilic 5-HMT because of a low activity of CYP2D6 (Diefenbach et al., 2008).

Tolterodine has no selectivity for muscarinic receptor subtypes but is claimed to have functional selectivity for the bladder over the salivary glands (Nilvebrant et al., 1997a; Stahl et al., 1995). In healthy volunteers, oral tolterodine at a high dose (6.4 mg) had a powerful inhibitory effect on micturition and also reduced stimulated salivation 1 hour after administration of the drug (Stahl et al., 1995). However, 5 hours after administration, the effects on the urinary bladder were maintained, whereas no significant effects on salivation could be demonstrated.

Animal experiments have suggested that antimuscarinics may affect signaling from the bladder (Andersson et al., 2011b). Vijaya et al. (2012) found confirming data in humans. In a randomized, placebo-controlled study, they evaluated the effect of tolterodine on urethral and bladder afferent nerves in women with DO compared with placebo, by studying the changes in the current perception threshold (CPT). They found a significantly increased CPT value at 5 Hz (described as urgency) and 250 Hz on both urethral and bladder stimulation after 1 week of treatment. When compared with placebo, women taking tolterodine had significantly increased bladder CPT values at 5 Hz ($P < .05$).

Tolterodine is available in IR (TOLT-IR; 1 or 2 mg; twice-daily administration) and ER (TOLT-ER) forms (2 or 4 mg; once-daily administration). The ER form seems to have advantages over the IR form in terms of both efficacy and tolerability (Van Kerrebroeck et al., 2001).

Several randomized, double-blind, placebo-controlled studies on patients with OAB and DO (both IDO and NDO) have documented a significant reduction in micturition frequency and number of incontinence episodes (Clemett and Jarvis, 2001; Hills et al., 1998; Salvatore et al., 2008). Comparative RCTs such as the OBJECT (Overactive Bladder: Judging Effective Control and Treatment) and OPERA (Overactive Bladder: Performance of Extended Release Agents) studies have further supported its effectiveness.

The OBJECT trial compared oxybutynin ER (OXY-ER) 10 mg once daily with TOLT-IR 2 mg twice daily (Appell et al., 2001) in a 12-week randomized, double-blind, parallel-group study including 378 patients with OAB. Participants had 7 to 50 episodes of urgency incontinence per week and 10 or more voids in 24 hours. The outcome measures were the number of episodes of urgency incontinence, total incontinence, and micturition frequency at 12 weeks adjusted for baseline. At the end of the study, OXY-ER was found to be significantly more effective than TOLT-IR in each of the main outcome measures adjusted for baseline (see the discussion of oxybutynin chloride later in this chapter). Dry mouth, the most common adverse event, was reported by 33% and 28% of participants taking OXY-ER and TOLT-IR, respectively. Rates of CNS and other adverse events were low and similar in both groups. The authors concluded that OXY-ER was more effective than TOLT-IR and that the rates of dry mouth and other adverse events were similar in both treatment groups.

In the OPERA study (Diokno et al., 2003), OXY-ER at 10 mg/day or TOLT-ER at 4 mg/day were given for 12 weeks to women with 21 to 60 urgency incontinence episodes per week and an average of 10 or more voids per 24 hours. Episodes of incontinence (primary end point), total incontinence (urgency and nonurgency), and micturition were recorded in seven 24-hour urinary diaries at baseline and at weeks 2, 4, 8, and 12 and compared. Adverse events were also evaluated. Improvements in weekly urgency incontinence episodes were similar for the 790 women who received OXY-ER (391) or TOLT-ER (399). OXY-ER was significantly more effective than TOLT-ER in reducing micturition frequency, and 23.0% of women taking OXY-ER reported no episodes of UI compared with 16.8% of women taking TOLT-ER. Dry mouth, usually mild, was more common with OXY-ER. In general, adverse events were mild and occurred at low rates, with both groups having similar discontinuation of treatment because of adverse events. The conclusions were that reductions in weekly urgency incontinence and total incontinence episodes were similar with the two drugs. Dry mouth was more common with OXY-ER, but tolerability was otherwise comparable, including adverse events involving the CNS.

In the Antimuscarinic Clinical Effectiveness Trial (ACET) (Sussman and Garely, 2002), which consisted of two trials, patients with OAB were randomized to 8 weeks of open-label treatment with either 2 mg or 4 mg of once-daily TOLT-ER (study one) and to 5 mg or 10 mg of OXY-ER (study two). In total, 1289 patients were included. Fewer patients prematurely withdrew from the trial in the TOLT-ER 4-mg group (12%) than either the OXY-ER 5-mg (19%) or OXY-ER 10-mg group (21%). More patients in the OXY-ER 10-mg group than in the TOLT-ER 4-mg group withdrew because of poor tolerability (13% vs. 6%). After 8 weeks, 70% of patients in the TOLT-ER 4-mg group perceived an improved bladder condition, compared with 60% in the TOLT-ER 2-mg group, 59% in the OXY-ER 5-mg group, and 60% in the OXY-ER 10-mg group. Dry mouth was dose-dependent with both agents, although differences between doses reached statistical significance only in the oxybutynin trial (OXY-ER 5 mg vs. OXY-ER 10 mg; $P = .05$). Patients treated with TOLT-ER 4 mg reported a significantly lower severity of dry mouth compared with OXY-ER 10 mg. The conclusion that the findings suggest improved clinical efficacy of TOLT-ER (4 mg) than of OXY-ER (10 mg) is weakened by the open-label design of the study.

Zinner et al. (2002) evaluated the efficacy, safety, and tolerability of TOLT-ER in older (≥65) and younger (<65) OAB patients, in a 12-week RCT including 1015 patients with urgency incontinence and urinary frequency. Patients were randomized to treatment with TOLT-ER 4 mg once daily (507) or placebo (508) for 12 weeks. Efficacy, measured with micturition charts (incontinence episodes, micturitions, volume voided per micturition) and subjective patient assessments; safety; and tolerability end points were evaluated relative to placebo. Compared with placebo, significant improvements in micturition chart variables with TOLT-ER showed no age-related differences. Dry mouth (of any severity) was the most common adverse event in both the TOLT-ER and placebo treatment arms, irrespective of age (<65: ER 22.7%, placebo 8.1%; ≥65: ER 24.3%, placebo 7.2%). A few patients (<2%) experienced severe dry mouth. No CNS (cognitive functions were not specifically studied), visual, cardiac (per ECG), or laboratory safety concerns were noted in this study. Withdrawal rates caused by adverse events on TOLT-ER 4 mg qd were comparable in the two age cohorts (<65: 5.5%; ≥65: 5.1%).

The central symptom in the OAB syndrome is urgency. Freeman et al. (2003) presented a secondary analysis of a double-blind, placebo-controlled study evaluating the effect of once-daily TOLT-ER on urinary urgency in patients with

OAB. Patients with urinary frequency (eight or more micturitions per 24 hours) and urgency incontinence (five or more episodes per week) were randomized to oral treatment with TOLT-ER 4 mg once daily ($n = 398$) or placebo ($n = 374$) for 12 weeks. Efficacy was assessed by use of patient perception evaluations. Of patients treated with TOLT-ER, 44% reported improved urgency symptoms (compared with 32% for placebo), and 62% reported improved bladder symptoms (placebo, 48%). The proportion of patients unable to hold urine on experiencing urgency was decreased by 58% with TOLT-ER, compared with 32% with placebo ($P < .001$).

In the Improvement in Patients: Assessing Symptomatic Control with Tolterodine ER (IMPACT) study, the efficacy of TOLT-ER for patients' most bothersome OAB symptom was investigated in an open-label primary care setting (Elinoff et al., 2006). Patients with OAB symptoms for 3 months or longer received TOLT-ER (4 mg once daily) for 12 weeks. By week 12, there were significant reductions in patients' most bothersome symptom: incontinence, urgency episodes, or nocturnal and daytime frequency. The most common adverse events were dry mouth (10%) and constipation (4%), and it was concluded that in primary care practice, bothersome OAB symptoms can be effectively and safely treated with TOLT-ER, even in patients with comorbid conditions.

Various aspects of the efficacy and tolerability of tolterodine have been further documented in a number of RCTs (Bharucha et al., 2008; Choo et al., 2008; Coyne et al., 2008; Dmochowski et al., 2007a, 2007b; Rogers et al., 2008; Rovner et al., 2008b; see also Chapple et al., 2008b; Novara et al., 2008). It is important to note that the QTc effects of tolterodine were determined in a crossover-designed QT study of recommended (2 mg twice daily) and supratherapeutic (4 mg twice daily) doses of tolterodine, moxifloxacin (400 mg once daily), and placebo. No subject receiving tolterodine exceeded the clinically relevant thresholds of 500-msec absolute QTc or 60-msec change from baseline, and it was concluded that tolterodine does not have a clinically significant effect on QT interval (Malhotra et al., 2007).

Olshansky et al. (2008) compared the effects on HR of TOLT-ER 4 mg/day with those of darifenacin 15 mg/day in healthy volunteers. They found that tolterodine, but not darifenacin, significantly increased mean HR per 24 hours. The proportion of subjects with an increase of more than 5 beats/min was significantly greater in those receiving TOLT-ER (25%) than with darifenacin (8.9%).

Hsiao et al. (2011) compared the urodynamic effects, therapeutic efficacy, and safety of solifenacin (5 mg) versus tolterodine ER (4 mg) treatment in women with the OAB syndrome. Both solifenacin and tolterodine had similar urodynamic effects, therapeutic efficacy, and adverse events; however, tolterodine had a greater effect in increasing HR than solifenacin.

In a prospective, open study, Song et al. (2006) compared the effects of bladder training (BT) and/or tolterodine as first-line treatment in female patients with OAB. One hundred and thirty-nine female patients with OAB were randomized to treatment with BT, tolterodine (2 mg twice daily), or both for 12 weeks. All treatments were effective; however, combination therapy was the most effective. Mattiasson et al. (2003) compared the efficacy of tolterodine 2 mg twice daily plus simplified BT with tolterodine alone in patients with OAB in a multicenter single-blind study. At the end of the study, the median percentage reduction in voiding frequency was greater with tolterodine plus BT than with tolterodine alone (33% vs. 25%; $P < .001$), whereas the median percentage increase in volume per void was 31% with tolterodine plus BT and 20% with tolterodine alone ($P < .001$). There was a median of 81% fewer incontinence episodes than at baseline with tolterodine alone, which was not significantly different from that with tolterodine plus BT (−87%). It was concluded that the effectiveness of tolterodine 2 mg twice daily can be augmented by a simplified BT regimen. However, Millard and the Asia Pacific Tolterodine Study Group (2004) investigated whether the combination of tolterodine plus a simple pelvic floor muscle exercise program would provide improved treatment benefits compared with tolterodine alone in 480 patients with OAB. Tolterodine therapy for 24 weeks resulted in significant improvement in urgency, frequency, and incontinence; however, no additional benefit was demonstrated for a simple pelvic floor muscle exercise program. In a 16-week, multicenter, open-label study, tolterodine ER plus behavioral intervention resulted in high treatment satisfaction and improved bladder diary variables in patients who had previously been treated and were dissatisfied with tolterodine or other antimuscarinics (Klutke et al., 2009).

More recently, the combination of intravaginal estradiol and tolterodine has been assessed to ascertain its impact on OAB (Ellington et al., 2016). After 12 weeks of monotherapy with either tolterodine ER 4 mg or estradiol, no significant differences in OABSS or bladder diary was seen between the groups, although within-group changes were observed. In the extension study, the addition of tolterodine ER to intravaginal estradiol significantly improved OAB symptom bother score when compared with estradiol alone (Ellington et al., 2016).

Abrams et al. (2006c) studied the safety and tolerability of tolterodine for the treatment of OAB symptoms in men with BOO. They found that tolterodine did not adversely affect urinary function in these men. Urinary flow rate was unaltered, and there was no evidence of clinically meaningful changes in voiding pressure and PVR or urinary retention. It was suggested that antimuscarinics can be safely administered in men with BOO. Lee et al. (2008a) reviewed the safety and efficacy of antimuscarinic agents in treating men with BOO and OAB and emphasized their safety and efficacy. They also concluded that combination therapy with antimuscarinics and α_1-adrenoceptor (α_1-AR) antagonists improves the symptoms effectively without increasing the incidence of acute urinary retention (AUR).

The beneficial effect of TOLT-ER in men with BPE and LUTS, including OAB, has been well documented. Both as monotherapy, but particularly in combination with α_1-AR antagonists, TOLT-ER was found effective (Höfner et al., 2007; Kaplan et al., 2006, 2008a, 2008b; Roehrborn et al., 2008a; Rovner et al., 2008a). This effect was obtained irrespective of prostate size and was not associated with increased incidence of AUR (Roehrborn et al., 2008a). A large, 26-week, multicenter, randomized, double-blind, placebo-controlled, three-period crossover study enrolled women 18 years of age and older who were diagnosed with OAB and reported eight or more micturitions per 24 hours and four or more urgency episodes per week in a 5-day bladder diary at baseline (Marencak et al., 2011). Patients were randomized to 1 of 10 treatment sequences and received three of five treatments, each for 4 weeks with 4-week washout periods: standard-dose pregabalin/tolterodine ER (150 mg bid/4 mg qd; $n = 102$); pregabalin alone (150 mg bid; $n = 105$); tolterodine ER alone (4 mg qd; $n = 104$); low-dose pregabalin/tolterodine ER (75 mg bid/2 mg qd; $n = 105$); and placebo ($n = 103$). Patients completed 5-day diaries at the end of treatment and washout periods. The primary end point was change from baseline to week 4 in MVV per micturition. Baseline-adjusted changes in MVV were significantly greater after treatment with standard-dose pregabalin/tolterodine ER (39.5 mL) versus tolterodine ER alone (15.5 mL; $P < .0001$) and with pregabalin alone (27.4 mL) versus tolterodine ER alone ($P = .005$) and placebo (11.9 mL; $P = .0006$). Treatments were generally well tolerated; discontinuation rates because of adverse events were 4%, 2%, 5%, 0%, and 1% with standard- and low-dose pregabalin/tolterodine ER, pregabalin, tolterodine ER, and placebo, respectively.

For more information, see the discussion of combination therapies in the New Developments section later in this chapter.

Dmochowski et al. (2014) assessed a new formulation of IR tolterodine 2 mg with sustained-release (SR) pilocarpine 9 mg twice daily. In this double-blind crossover trial with open-label extension, a combination of tolterodine and pilocarpine and tolterodine alone were better than placebo at improving daily incontinence and micturition episodes, however, they were no different when compared with each other. Dry mouth as assessed by visual analog scale (VAS; 0–100) were 20.9, 28.7, and 40.4 for placebo, tolterodine/pilocarpine, and tolterodine alone, respectively. Other parameters such as general discomfort around the mouth and difficulty swallowing/chewing showed similar trends. The incidence of dry mouth with tolterodine/pilocarpine was similar to placebo (3.9% vs. 5.3%). In the extension study, patients were randomized to tolturodine 3 mg and pilocarpine 13.5 mg twice daily or tolterodine ER 4 mg once daily. Incidence of dry mouth were similar in the two groups despite the tolterodine/pilocarpine combination having 50% more tolterodine (Dmochowski et al., 2014).

Assessment.

Both the IR and ER forms of tolterodine have a well-documented effect in OAB and DO (see Table 120.3) and are well tolerated.

Trospium Chloride.

Trospium is a quaternary ammonium compound with a biologic availability of less than 10% (Doroshyenko et al., 2005; Fusgen and Hauri, 2000). The drug has a plasma half-life of approximately 20 hours and is **mainly (60% of the dose absorbed) eliminated unchanged in urine.** The concentration obtained in urine seems to be enough to affect the mucosal signaling system in a rat model (Kim et al., 2006). Whether or not it contributes to the clinical efficacy of the drug remains to be established.

Trospium is not metabolized by the cytochrome P450 enzyme system (Beckmann-Knopp et al., 1999; Doroshyenko et al., 2005)**. It is expected to cross the blood-brain barrier to a limited extent** because it is a substrate for the drug-efflux transporter P-glycoprotein, which restricts its entry into the brain (Davis et al., 2014). This was demonstrated by Staskin et al. (2010), who showed that trospium chloride levels in cerebrospinal fluid (CSF) samples were undetectable on day 10 at steady-state peak plasma concentration concurrent with measureable peak plasma values. Clinically, trospium seems to have no negative cognitive effects (Chancellor et al., 2012; Fusgen and Hauri, 2000; Staskin et al., 2010; Todorova et al., 2001; Wiedemann et al., 2002).

Trospium has no selectivity for muscarinic receptor subtypes. In isolated detrusor muscle, it was more potent than oxybutynin and tolterodine to antagonize carbachol-induced contractions (Uckert et al., 2000).

Several RCTs have documented positive effects of trospium both in NDO (Madersbacher et al., 1995; Menarini et al., 2006; Stöhrer et al., 1991) and non-neurogenic DO (Alloussi et al., 1998; Cardozo et al., 2000; Dmochowski et al., 2008; Halaska et al., 2003; Jünemann and Al-Shukri, 2000; Rudy et al., 2006; Staskin et al., 2007; Zinner et al., 2004). In a placebo-controlled, double-blind study on patients with NDO, the drug was given twice daily at a dose of 20 mg over a 3-week period (Stöhrer et al., 1991). It increased maximum cystometric capacity, decreased maximal detrusor pressure, and increased compliance in the treatment group, whereas no effects were noted in the placebo group. Side effects were few and comparable in both groups. In another RCT including patients with spinal cord injuries and NDO, trospium and oxybutynin were equieffective; however, trospium seemed to have fewer side effects (Madersbacher et al., 1995).

The effect of trospium in urgency incontinence has been documented in several RCTs. Alloussi et al. (1998) compared the effects of the drug with those of placebo in 309 patients in a urodynamic study of 3 weeks’ duration. Trospium 20 mg was given twice daily. Significant increases were noted in volume at first involuntary contraction and in maximum bladder capacity. Cardozo et al. (2000) investigated 208 patients with DO who were treated with trospium 20 mg twice daily for 2 weeks. Also in this study, significant increases were found in mean volume at first unstable contraction (from 233 to 299 mL; placebo, 254 to 255 mL) and in maximum bladder capacity (from 329 to 356 mL; placebo, 345 to 335 mL) in the trospium-treated group. Trospium was well tolerated with similar frequency of adverse effects as in the placebo group. Jünemann and Al-Shukri (2000) compared trospium 20 mg twice daily with tolterodine 2 mg twice daily in a placebo-controlled, double-blind study on 232 patients with urodynamically proven DO, urgency incontinence without demonstrable DO, or mixed incontinence. Trospium reduced the frequency of micturition, which was the primary end point, more than tolterodine and placebo, and also reduced the number of incontinence episodes more than the comparators. Dry mouth was comparable in the trospium and tolterodine groups (7% and 9%, respectively).

Halaska et al. (2003) studied the tolerability and efficacy of trospium chloride in doses of 20 mg twice daily for long-term therapy in patients with urgency syndrome. The trial included a total of 358 patients with urgency syndrome or urgency incontinence. After randomization in the ratio of 3 : 1, participants were treated continuously for 52 weeks with either trospium chloride (20 mg twice daily) or oxybutynin (5 mg twice daily). Urodynamic measurements were performed at the beginning and at 26 and 52 weeks to determine the maximal cystometric bladder capacity. Analysis of the micturition diary clearly indicated a reduction in the micturition frequency, incontinence frequency, and the number of urgency episodes in both treatment groups. Mean maximum cystometric bladder capacity increased during treatment with trospium chloride by 92 mL after 26 weeks and 115 mL after 52 weeks ($P = .001$). Further comparison with oxybutynin did not reveal any statistically significant differences in urodynamic variables between the drugs. Adverse events occurred in 65% of the patients treated with trospium and 77% of those treated with oxybutynin. The main symptom encountered in both treatment groups was dry mouth. An overall assessment for each of the drugs revealed a comparable efficacy level and a better benefit-risk ratio for trospium than for oxybutynin resulting from better tolerability.

Zinner et al. (2004) treated 523 patients with symptoms associated with OAB and urgency incontinence with 20 mg trospium twice daily or placebo in a 12-week, multicenter, parallel, double-blind, placebo-controlled trial. Dual primary end points were change in average number of toilet voids and change in urgency incontinence episodes per 24 hours. Secondary efficacy variables were change in average volume per void, voiding urgency severity, urinations during day and night, time to onset of action, and change in Incontinence Impact Questionnaire score. By week 12, trospium significantly decreased average frequency of toilet voids per 24 hours (−2.37) and urgency incontinence episodes 59% compared with placebo (−1.29; 44%). It significantly increased average volume per void (32 mL; placebo, 7.7 mL) and decreased average urgency severity and daytime frequency. All effects occurred by week 1, and all were sustained throughout the study. Nocturnal frequency decreased significantly by week 4 (−0.43; placebo, −0.17), and Incontinence Impact Questionnaire scores improved at week 12. Trospium was well tolerated. The most common side effects were dry mouth (21.8%; placebo 6.5%), constipation (9.5%; placebo 3.8%), and headache (6.5%; placebo 4.6%). In a large US multicenter trial with the same design and including 658 patients with OAB, Rudy et al. (2006) confirmed the data by

Zinner et al. (2004), with respect to both efficacy and adverse effects.

Dose escalation seems to improve therapeutic efficacy. In a 12-week, randomized, double-blind, phase IIIb study including 1658 patients with urinary frequency plus urgency incontinence, patients received trospium chloride 15 mg tid ($n = 828$) or 2.5 mg oxybutynin hydrochloride tid ($n = 830$). After 4 weeks, daily doses were doubled and not readjusted in 29.2% (242 of 828) of patients in the trospium group and in 23.3% (193 of 830) in the oxybutynin group, until the end of treatment. At study end, there were no relevant differences between the "dose adjustment" subgroups and the respective "no dose adjustment" subgroups (trospium, $P = .249$; oxybutynin, $P = .349$). After dose escalation, worsening of dry mouth was higher in both dose-adjusted subgroups compared with the respective "no dose adjustment" subgroups ($P < .001$). Worsening of dry mouth was lower in the trospium groups than in the oxybutynin groups (Bödeker et al., 2010).

An ER formulation of trospium allowing once-daily administration has been introduced (Silver et al., 2010), and its effects have been tested in controlled trials (Chancellor et al., 2010; Dmochowski et al., 2008; MacDiarmid et al., 2011; Sand et al., 2011a, 2011b; Staskin et al., 2007; Zinner et al., 2011). These studies demonstrated similar efficacy as found with previous formulations, but include experiences in, for example, elderly patients (>75 years), obese patients, and patients who use multiple concomitant medications. The most frequent side effects were dry mouth (12.9%; placebo, 4.6%) and constipation (7.5%; placebo, 1.8%) (Dmochowski et al., 2008).

Intravesical application of trospium may be an interesting alternative. Fröhlich et al. performed a randomized, single-blind, placebo-controlled, monocenter clinical trial in 84 patients with urgency or urgency incontinence (Fröhlich et al., 1998). Compared with placebo, intravesical trospium produced a significant increase in maximum bladder capacity and a decrease in detrusor pressure accompanied by an increase in residual urine. There was an improvement in uninhibited bladder contractions. No adverse events were reported. It is interesting to note that intravesical trospium does not seem to be absorbed (Walter et al., 1999), thus offering an opportunity for treatment with minimal systemic antimuscarinic effects.

Assessment.

Trospium has a well-documented effect in OAB and DO, and tolerability and safety seem acceptable (see Table 120.3).

Antimuscarinics With “Mixed” Action

Some drugs used for treatment of OAB and DO have been shown to have more than one mechanism of action. They all have a more-or-less pronounced antimuscarinic effect and an often poorly defined “direct” action on bladder muscle. For several of these drugs, the antimuscarinic effects can be demonstrated at much lower drug concentrations than the direct action, which may involve blockade of voltage-gated Ca^{2+} channels. Most likely the clinical effects of these drugs can be explained mainly by an antimuscarinic action. Among the drugs with mixed actions was terodiline, which was withdrawn from the market because it was suspected to cause polymorphic ventricular tachycardia (torsades de pointes) in some patients (Connolly et al., 1991; Stewart et al., 1992).

Oxybutynin Chloride.

Oxybutynin is a tertiary amine that is well absorbed and undergoes extensive upper gastrointestinal and first-pass hepatic metabolism via the cytochrome P450 system (CYP3A4) into multiple metabolites. The primary metabolite, *N*-desethyloxybutynin, has pharmacologic properties similar to those of the parent compound (Waldeck et al., 1997) **but occurs in much higher concentrations after oral administration** (Hughes et al., 1992)**. It has been implicated as the major cause of the troublesome side effect of dry mouth associated with the administration of oxybutynin.** It seems reasonable to assume that the effect of oral oxybutynin to a large extent is exerted by the metabolite. The occurrence of an active metabolite may also explain the lack of correlation between plasma concentration of oxybutynin itself and side effects in geriatric patients reported by Ouslander et al. (1988). The plasma half-life of the oxybutynin is approximately 2 hours, but with wide interindividual variation (Douchamps et al., 1988; Hughes et al., 1992).

Oxybutynin has several pharmacologic effects in vitro, some of which seem difficult to relate to its effectiveness in the treatment of DO. **It has both an antimuscarinic and a direct muscle relaxant effect and, in addition, local anesthetic action. The latter may be of importance when the drug is administered intravesically, but probably play no role when it is given orally. In vitro, oxybutynin was 500 times weaker as a smooth muscle relaxant than as an antimuscarinic agent** (Kachur et al., 1988)**. Most likely, when given systemically, oxybutynin acts mainly as an antimuscarinic drug.** Oxybutynin has a high affinity for muscarinic receptors in human bladder tissue and effectively blocks carbachol-induced contractions (Nilvebrant and Sparf, 1988; Waldeck et al., 1997). **The drug was shown to have slightly higher affinity for muscarinic M_1 and M_3 receptors than for M_2 receptors** (Nilvebrant and Sparf, 1986; Norhona-Blob and Kachur, 1991), but the clinical significance of this is unclear.

The IR form of oxybutynin (OXY-IR) is recognized for its efficacy, and most of the newer antimuscarinic agents have been compared with it once efficacy over placebo has been determined. In general, the new formulations of oxybutynin and other antimuscarinic agents offer patients efficacy roughly equivalent to that of OXY-IR, and the advantage of the newer formulations lies in improved dosage schedules and side-effect profiles (Appell et al., 2001; Diokno et al., 2003; Dmochowski et al., 2002). An OXY-ER once-daily oral formulation and an oxybutynin transdermal delivery system (OXY-TDS) are available. OXY-TDS offers a twice-weekly dosage regimen and the potential for improved patient compliance and tolerability. McCrery and Appell overviewed (2006) some of the available formulations of oxybutynin.

Immediate-Release Oxybutynin.

Several controlled studies have shown that OXY-IR is effective in controlling DO, including NDO (Andersson and Chapple, 2001; Yarker et al., 1995). The recommended oral dose of the IR form is 5 mg three times daily or four times daily, even if lower doses have been used. Thüroff et al. (1998) summarized 15 RCTs on a total of 476 patients treated with oxybutynin. The mean decrease in incontinence was recorded as 52%, and the mean reduction in frequency per 24 hours was 33% (data on placebo not presented). The overall “subjective improvement” rate was reported as 74% (range 61% to 100%). The mean percent of patients reporting an adverse effect was 70% (range 17% to 93%). Oxybutynin 7.5 to 15 mg/day significantly improved QoL of patients with OAB in a large open multicenter trial. In this study, patient compliance was 97%, and side effects, mainly dry mouth, were reported by only 8% of the patients (Amarenco et al., 1998). In 75 nursing home residents, Ouslander et al. (1995) found that oxybutynin did not add to the clinical effectiveness of prompted voiding in a placebo-controlled, double-blind, crossover trial. On the other hand, in another controlled trial in 57 elderly subjects, oxybutynin with BT was found to be superior to BT alone (Szonyi et al., 1995).

Several open studies in patients with spinal cord injuries suggested that oxybutynin, given orally or intravesically, can be of therapeutic benefit (Kim et al., 1996; Szollar and Lee, 1996).

The therapeutic effect of OXY-IR on DO is associated with a high incidence of side effects (up to 80% with oral administration). These are typically antimuscarinic in nature (dry mouth, constipation, drowsiness, blurred vision) and are often dose limiting (Baigrie et al., 1988; Jonville et al., 1992). The effects of oxybutynin on ECG were studied in elderly patients with UI (Hussain et al., 1996); no changes were found. It cannot be excluded that the commonly recommended dose of 5 mg × 3 is unnecessarily high in some patients, and that a starting dose of 2.5 mg × 2 with subsequent dose titration would reduce the number of adverse effects (Amarenco et al., 1998).

Extended-Release Oxybutynin.

The OXY-ER formulation was developed to decrease liver metabolite formation of desethyloxybutynin (DEO) with the presumption that it would result in decreased side effects, especially dry mouth, and improve patient compliance with remaining on oxybutynin therapy (Arisco et al., 2009). The formulation uses an osmotic system to release the drug at a controlled rate over 24 hours distally primarily into the large intestine where absorption is not subject to first-pass metabolism in the liver. This reduction in metabolism is meant to improve the rate of dry mouth complaints when compared with OXY-IR. DEO is still formed through the hepatic cytochrome P450 enzymes, but clinical trials have indeed demonstrated improved dry mouth rates compared with OXY-IR (Appell et al., 2003). Salivary output studies have also been interesting. Two hours after administration of OXY-IR or TOLT-IR, salivary production decreased markedly and then gradually returned to normal. With OXY-ER, however, salivary output was maintained at predose levels throughout the day (Chancellor et al., 2001).

The effects of OXY-ER have been well documented (Siddiqui et al., 2004). In the OBJECT study, the efficacy and tolerability of 10-mg OXY-ER was compared with a twice-daily 2-mg dose of TOLT-IR (Appell et al., 2001). OXY-ER was statistically more effective than TOLT-IR in weekly urgency incontinence episodes (OXY-ER from 25.6% to 6.1%; TOLT-IR 24.1% to 7.8%), total incontinence (OXY-ER from 28.6% to 7.1%; TOLT-IR 27.0% to 9.3%), and frequency (OXY-ER 91.8% to 67.1%; TOLT-IR 91.6% to 71.5%), and both medications were equally well tolerated. The basic study was repeated as the OPERA study, with the difference that this study was a direct comparison of the two ER forms, OXY-ER (10 mg) and TOLT-ER (4 mg), and the results were quite different (Diokno et al, 2003). In this study, there was no significant difference in efficacy for the primary end point of urgency incontinence; however, TOLT-ER had a statistically lower incidence of dry mouth. OXY-ER 10 mg was statistically better than TOLT-ER 4 mg in only reduction of the rate of urinary frequency. These studies made it clear that in comparative studies, IR entities of one drug should no longer be compared with ER entities of the other.

Greater reductions in urgency and total incontinence have been reported in patients treated in dose-escalation studies with OXY-ER. In two randomized studies, the efficacy and tolerability of OXY-ER were compared with those of OXY-IR. In the 1999 study, 105 patients with urgency or mixed incontinence were randomized to receive 5 to 30 mg of OXY-ER once daily or 5 mg of OXY-IR one to four times a day (Anderson et al., 1999). Dose titrations began at 5 mg, and the dose was increased every 4 to 7 days until one of three end points was achieved. These were (1) the patient reported no urgency incontinence during the final 2 days of the dosage period; (2) the maximum tolerable dose was reached; or (3) the maximum allowable dose (30 mg for OXY-ER or 20 mg for OXY-IR) was reached. The mean percent reduction in weekly urgency and total incontinence episodes was statistically similar between OXY-ER and OXY-IR, but dry mouth was reported statistically more often with OXY-IR. In the 2000 study, 226 patients were randomized between OXY-ER and OXY-IR with weekly increments of 5 mg daily up to 20 mg daily (Versi et al., 2000). As in the 1999 study, OXY-ER again achieved a greater than 80% reduction in urgency and total incontinence episodes, and a significant percentage of patients became dry. A negative aspect of these studies is that there were no naïve patients included; all patients were known responders to oxybutynin. Similar efficacy results have been achieved, however, with OXY-ER in a treatment-naïve population (Gleason et al., 1999).

In an RCT comparing different daily doses of oxybutynin (5, 10, and 15 mg), Corcos et al. found a significant dose-response relationship for both urgency incontinence episodes and dry mouth (Corcos et al., 2006). The greatest satisfaction was with 15 mg of oxybutynin per day.

In a multicenter, prospective, observational, flexible-dosing Korean study, Yoo et al. (2012) investigated the prescription pattern and dose distribution of OXY-ER in patients with OAB syndrome in actual clinical practice. The dose for each patient was adjusted after discussions of efficacy and tolerability between doctor and patient, over a 12-week treatment period. Efficacy was measured by administering the Primary OAB Symptom Questionnaire (POSQ) before and after treatment. Patients were also administered a patient perception of treatment benefit (PPTB) questionnaire at the end of the study. Of the 809 patients enrolled, 590 (73.2%) continued to take study medication for 12 weeks. Most patients were prescribed 5 to 10 mg of oxybutynin ER per day as both starting and maintenance doses, with a dose escalation rate of only 14.9%. All OAB symptoms evaluated by the POSQ were improved; 94.1% of patients reported benefits from treatment, and 89.3% were satisfied.

Transdermal Oxybutynin.

Transdermal delivery also alters oxybutynin metabolism, reducing DEO production to an even greater extent than OXY-ER. A study comparing OXY-TDS with OXY-IR demonstrated a statistically equivalent reduction in daily incontinence episodes (from 7.3 to 2.3 [66%] for OXY-TDS; and 7.4 to 2.6 [72%] for OXY-IR), but much less dry mouth (38% for OXY-TDS and 94% for OXY-IR) (Davila et al., 2001). In another study, the 3.9-mg daily-dose patch significantly (vs. placebo) reduced the mean number of daily incontinence episodes (from 4.7 to 1.9; placebo 5.0 to 2.9) while reducing average daily urinary frequency, confirmed by an increased average voided volume (from 165 to 198 mL; placebo 175 to 182 mL) (Dmochowski et al., 2002). Furthermore, dry mouth rate was similar to placebo (7% vs. 8.3%). In a third study, OXY-TDS was compared not only with placebo but with TOLT-ER (Dmochowski et al., 2003b). Both drugs equivalently and significantly reduced daily incontinence episodes and increased the average voided volume, but TOLT-ER was associated with a significantly higher rate of antimuscarinic adverse events. **The primary adverse event for OXY-TDS was application site reaction pruritus in 14% and erythema in 8.3%, with nearly 9% feeling that the reactions were severe enough to withdraw from the study** despite the lack of systemic problems.

The pharmacokinetics and adverse effect dynamics of OXY-TDS (3.9 mg/day) and OXY-ER (10 mg/day) were compared in healthy subjects in a randomized, two-way crossover study (Appell et al., 2003). Multiple blood and saliva samples were collected and pharmacokinetic parameters and total salivary output were assessed. OXY-TDS administration resulted in greater systemic availability and minimal metabolism to DEO compared with OXY-ER, which resulted in greater salivary output in OXY-TDS patients and less dry mouth symptomatology than when taking OXY-ER.

Dmochowski et al. (2005) analyzed the combined results of two RCTs and concluded that transdermal oxybutynin was shown to be efficacious and well tolerated. The most common systemic side effect was dry mouth (7.0% vs. placebo 5.3%). Application site erythema occurred in 7% and pruritus in 16.1%. Also, Cartwright and Cardozo (2007)reviewed published and presented data and concluded that transdermal oxybutynin has a good balance between efficacy and tolerability with a rate of systemic antimuscarinic side effects that is lower than with oral antimuscarinics; however, this benefit was offset by the rate of local skin reaction (Cartwright and Cardozo, 2007). The reviews by Sahai et al. and Staskin and Salvatore largely confirmed these conclusions, which also have been supported by further studies (Sahai et al., 2008; Staskin and Salvatore, 2010; Cartwright et al., 2011).

In a Japanese OAB population, an alternative daily 73.5-mg transdermal oxybutynin patch was assessed against propiverine 20 mg daily and placebo (Yamaguchi et al., 2014). Approximately 570 patients were in the active arms and 380 in placebo. At 12 weeks, the oxybutynin patch was significantly superior than placebo and noninferior to propiverine for daily micturition episodes. Urgency and voided volume was better compared with placebo for transdermal oxybutynin, however, urgency incontinence episodes and nocturia were no different. Furthermore 8 of 9 domains assessed utilizing the KHQ were better for transdermal oxybutynin compared with placebo, suggesting better QoL in this group. Dry mouth and constipation were seen in 6.5% and 0.7%, 13.2% and 5%, and 1.8% and 1% in the transdermal oxybutynin, propiverine and placebo groups, respectively. In the transdermal oxybutynin group, application site dermatitis was seen in 31.8%, with site erythema in 5.6%.

The transdermal patch (3.9 mg/day) has been shown to be subjectively effective in a small pediatric population but with 35% skin site irritation and 20% discontinuation rate (Gleason et al., 2014).

Oxybutynin Topical Gel.

Given the efficacy and tolerability of the transdermal application, limited only by skin site reactions, a gel formulation was developed. Oxybutynin topical gel (OTG) was approved by the U.S. Food and Drug Administration (FDA) in January 2009. OTG is applied once daily to the abdomen, thigh, shoulder, or upper arm area (Staskin et al., 2009). The 1-g application dose delivers approximately 4 mg of drug to the circulation, with stable plasma concentrations and a “favorable” *N*-desethyloxybutynin metabolite–oxybutynin ratio, believed to minimize the antimuscarinic side effects (Staskin and Robinson, 2009). In a multicenter RCT, 789 patients (89% women) with urgency-predominant incontinence were assigned to OTG or placebo once daily for 12 weeks (Staskin et al., 2009). The mean number of urgency episodes, as recorded by a 3-day voiding diary, was reduced by 3.0 episodes per day versus 2.5 in the placebo arm ($P < .0001$). Urinary frequency decreased by 2.7 episodes per day, and voided volume increased by 21 mL (vs. 2.0 episodes [$P = .0017$] and 3.8 mL [$P = .0018$], respectively, in the placebo group). Dry mouth was reported in 6.9% of the treatment group versus 2.8% of the placebo group. Skin reaction at the application site was reported in 5.4% of the treatment group versus 1.0% in the placebo arm. It was felt that improved skin tolerability of the gel over the OXY transdermal patch delivery system was secondary to lack of adhesive and skin occlusion. The gel dries rapidly on application and leaves no residue; person-to-person transference via skin contact is largely eliminated if clothing is worn over the application site (Dmochowski et al., 2011). The evolution of the transdermal gel allows greater patient tolerability and improved compliance. This was confirmed by Sand et al. (2012a), who showed that in 704 women with OAB, OTG significantly reduced the number (mean ± standard deviation [SD]) of daily incontinence episodes (OTG, −3.0 ± 2.8 episodes; placebo, −2.5 ± 3.0 episodes), reduced urinary frequency, increased voided volume, and improved select health-related QoL domains versus placebo. Dry mouth was the only drug-related adverse event significantly more common with OTG (7.4%) than with placebo (2.8%).

A newer 3% topical oxybutynin gel has been assessed in a phase III randomized placebo-controlled trial (randomized $n = 626$) (Goldfischer et al., 2015). This product is administered via a metered-dose pump dispenser and was hypothesized to have less adverse events. Furthermore, it is made with propylene glycol to help with skin permeation. Two doses of 84 mg/day and 56 mg/day of the 3% topical oxybutynin were assessed against placebo gel in this population of patients with urgency and/or urge-predominant mixed incontinence. The 84 mg/day dose was statistically better than placebo after 12 weeks in improving weekly UI episodes (primary end point) and also daily urinary frequency and urine voided volumes. The lower dose of 56 mg/day was not statistically better than placebo. Dry mouth and application site erythema was seen in 12.1% and 3.3% in the 84 mg/day group compared with 5% and 0.5% in the placebo arm.

Other Administration Forms.

Rectal administration was reported to have fewer adverse effects than the conventional tablets (Collas and Malone-Lee, 1997).

Administered intravesically, oxybutynin has in several studies been demonstrated to increase bladder capacity and produce clinical improvement with few side effects, both in neurogenic and in other types of DO, and in both children and adults (Fader et al., 2007; George et al., 2007; Guerra et al., 2008; Lose and Norgaard, 2001), although adverse effects may occur (Kasabian et al., 1994; Palmer et al., 1997). More recently a phase II exploratory randomized placebo-controlled trial (*n* = 323) of intravaginal oxybutynin ring was conducted based on the premise that there is a shared lymphovascular network between the vagina and bladder (Gittelman et al. 2014). Approximately one-fourth of the patients had an accidental fallout of the ring. Both formulations of 4 and 6 mg were better than placebo at reducing weekly UI episodes when compared with placebo. Dry rates, frequency, and UUI episodes were also statistically better in the 6-mg intravaginal oxybutynin group compared with placebo. UTI, dry mouth, and vaginal discharge were the most common adverse events. UTI and dry mouth rates were 11.6% and 10.2% in the 6-mg oxybutynin group, 9.1% and 4.9% in the 4-mg oxybutynin group and 4.5% and 2.6% in the placebo groups.

Effects on Cognition.

Several studies have documented the possibility that oxybutynin may have negative effects on cognitive functions, particularly in the elderly population but also in children (Kay and Ebinger, 2008; Kay et al., 2006; Klausner and Steers, 2007). This factor should be taken into consideration when prescribing the drug.

Assessment.

Oxybutynin has well-documented efficacy in the treatment of OAB and DO (see Table 120.3). Despite the adverse-effect profile, it is still an established therapeutic option.

Propiverine Hydrochloride.

Madersbacher and Murz reviewed several aspects of the preclinical, pharmacokinetic, and clinical effects of propiverine (Madersbacher and Murz, 2001). The drug is rapidly absorbed (Tmax 2 hours) but has a high first-pass metabolism, and its biologic availability is about 50%. Propiverine is an inducer of hepatic cytochrome P450 enzymes in rats in doses about 100 times above therapeutic doses in humans (Walter et al., 2003). Several active metabolites that quantitatively and qualitatively differ from the mother compound are formed

(Haustein et al., 1988; Müller et al., 1993; Sugiyama et al., 2008; Wuest et al., 2006; Zhu et al., 2008). Most likely these metabolites contribute to the clinical effects of the drug, but their individual contributions have not been clarified (Michel and Hegde, 2006). The half-life of propiverine itself is about 11 to 14 hours. An ER preparation was shown to be effective (Jünemann et al., 2006; May et al., 2008). Oral absorption of propiverine is site dependent and influenced by dosage form and circadian time–dependent elimination processes (May et al., 2008).

Propiverine has combined antimuscarinic and calcium antagonistic actions (Haruno, 1992; Tokuno et al., 1993)**. The importance of the calcium antagonistic component for the drug's clinical effects has not been established. Propiverine has no selectivity for muscarinic receptor subtypes.** Christ et al. (2008) investigated the effects of propiverine on cardiac ion channels and action potentials. In a concentration-dependent manner, propiverine blocked ihERG channels expressed in HEK293 cells, and native I(Kr) current in ventricular myocytes of guinea pig. However, action potential duration was not prolonged in guinea pig and human ventricular tissue, and the investigators concluded that their results did not provide evidence for an enhanced cardiovascular safety risk with the drug.

Propiverine has been shown to have beneficial effects in patients with DO in several investigations. Thüroff et al. (1998) analyzed nine randomized studies on a total of 230 patients and found a 17% reduction in micturitions per 24 hours, a 64-mL increase in bladder capacity, and a 77% (range 33% to 80%) subjective improvement. Side effects were found in 14% (range 8% to 42%). In patients with NDO, controlled clinical trials have demonstrated propiverine's superiority over placebo (Stöhrer et al., 1999). Propiverine also increased bladder capacity and decreased maximum detrusor contractions. Controlled trials comparing propiverine, flavoxate, and placebo (Wehnert et al., 1989) and propiverine, oxybutynin, and placebo (Madersbacher et al., 1999; Wehnert et al., 1992) have confirmed the efficacy of propiverine, and suggested that the drug may have equal efficacy and fewer side effects than oxybutynin. In a comparative RCT including 131 patients with NDO, propiverine and oxybutynin were compared (Stöhrer et al., 2007). The drugs were found to be equally effective in increasing bladder capacity and lowering bladder pressure. Propiverine caused a significantly lower frequency of dry mouth than oxybutynin.

Also in children and adolescents with NDO, propiverine was found to be effective (Grigoleit et al., 2006; Schulte-Baukloh et al., 2006), with a low incidence rate of adverse events (<1.5%) (Grigoleit et al., 2006). Marschall-Kehrel et al. (2009) performed a randomized, double-blind, placebo-controlled trial with parallel-group design in children 5 to 10 years of age. Of 171 randomized children, 87 were treated with propiverine and 84 with placebo. Decrease in voiding frequency per day was the primary efficacy parameter; secondary end points included voided volume and incontinence episodes. There was a significant decrease in voiding frequency episodes for propiverine versus placebo. Superiority could also be demonstrated for voided volume and incontinence episodes per day. Propiverine was well tolerated; 23% of patients reported side effects for propiverine and 20% for placebo.

In a randomized, double-blind, multicenter clinical trial, patients with IDO were treated with 15 mg of propiverine twice daily or 2 mg of TOLT-IR twice daily over a period of 28 days (Jünemann et al., 2005). The maximum cystometric capacity was determined at baseline and after 4 weeks of therapy. The difference of both values was used as the primary end point. Secondary end points were voided volume per micturition, evaluation of efficacy (by the investigator), tolerability, PVR volume, and QoL. It was found that the mean maximum cystometric capacity increased significantly ($P < .01$) in both groups. The volume at first urgency and the frequency and volume chart parameters also showed relevant improvements during treatment. The most common adverse event, dry mouth, occurred in 20 patients in the propiverine group and in 19 patients in the tolterodine group. The scores for QoL improved comparably in both groups.

Madersbacher et al. (1999) compared the tolerability and efficacy of propiverine (15 mg three times daily), oxybutynin (5 mg twice daily), and placebo in 366 patients with urgency and urgency incontinence in a randomized, double-blind, placebo-controlled clinical trial. Urodynamic efficacy of propiverine was judged similar to that of oxybutynin, but the incidence of dry mouth and the severity of dry mouth were judged to be less with propiverine than with oxybutynin. Dorschner et al. (2000) investigated in a double-blind, multicenter, placebo-controlled, randomized study the efficacy and cardiac safety of propiverine in 98 elderly patients (mean age 68 years) with urgency, urgency incontinence, or mixed urgency-stress incontinence. After a 2-week placebo run-in period, the patients received propiverine (15 mg three times daily) or placebo (three times daily) for 4 weeks. Propiverine caused a significant reduction of the micturition frequency (from 8.7 to 6.5) and a significant decrease in episodes of incontinence (from 0.9 to 0.3 per day). The incidence of adverse events was very low (2% dry mouth under propiverine—2 of 49 patients). Resting and ambulatory ECGs indicated no significant changes. Donath et al. (2011) further studied the cardiac safety of propiverine in two comprehensively designed monocentric ECG studies (including 24 healthy women, followed by a second study on 24 male patients with coronary heart disease (CHD) and a pathologic Pardee Q wave on the ECG). Both studies were placebo controlled and compared the effects of single-dose (30 mg sid) and multiple-dose (15 mg tid) administration of propiverine hydrochloride in a crossover design over 6 and 13 days, respectively. They were performed to investigate the influence of propiverine hydrochloride and its main metabolite, propiverine *N*-oxide, on cardiac function with regard to QTc prolongation, QTc dispersion, and T-wave shape. No negative effects on cardiac safety could be demonstrated.

Abrams et al. (2006b) compared the effects of propiverine and oxybutynin on ambulatory urodynamic monitoring (AUM) parameters, safety, and tolerability in OAB patients. Seventy-seven patients received two of the following treatments during two 2-week periods: propiverine 20 mg once daily, propiverine 15 mg three times daily, oxybutynin 5 mg three times daily, and placebo. The researchers found that oxybutynin 15 mg was more effective than propiverine 20 mg in reducing symptomatic and asymptomatic involuntary detrusor contractions in ambulatory patients. Oxybutynin had a higher rate of dry mouth, and propiverine had a more pronounced effect on gastrointestinal, cardiovascular, and visual function.

Yamaguchi et al. (2007) performed a multicenter, 12-week, double-blind phase III trial in Japanese men and women with OAB (1593 patients were randomized, and 1584 were treated), comparing solifenacin 5 or 10 mg, propiverine 20 mg, and placebo. Changes at end point in number of voids per 24 hours, urgency, incontinence, urgency incontinence, and nocturia episodes, volume per void, restoration of continence, and QoL were examined. It was found that at end point there were greater reductions in mean (SD) voids per 24 hours with all drug regimens than with placebo. All active treatments improved the volume voided and QoL versus placebo; solifenacin 10 mg reduced nocturia episodes and significantly improved urgency episodes and volume voided versus propiverine 20 mg, and solifenacin 5 mg caused less dry mouth. Solifenacin 10 mg caused more dry mouth and constipation than propiverine 20 mg. Wada et al. (2011) performed a prospective nonrandomized crossover study of female OAB patients, assigned alternately to treatment with propiverine (20 mg) for 8 weeks and then solifenacin (5 mg) for 8 weeks, or solifenacin for 8 weeks and then propiverine for 8 weeks. At baseline, 8th week, and 16th week, symptoms were assessed using the OABSS. Of the 121 patients enrolled, 83 were analyzed. Both drugs were effective. Urgency was further improved after switching from propiverine to solifenacin, but not after switching from solifenacin to propiverine. Solifenacin was better tolerated than propiverine.

In another multicenter, prospective, parallel, double-blind, placebo-controlled trial, Lee et al. (2010) studied the effects of 30 mg of propiverine per day in 264 OAB patients (mean age 52.2 years), 221 of whom had efficacy data available from baseline and at least one on-treatment visit with greater than 75% compliance. The study was focused on improving urgency. Overall, among patients treated with propiverine, 39% rated their treatment as providing "much benefit," compared with 15% in the placebo group. Adverse events reported by 32 (22.5%) and 10 (12.7%) patients in the propiverine and placebo group were all tolerable. The ER formulation of propiverine was compared with the ER formulation of tolterodine in a noninferiority trial with approximately 150 patients in each study arm (Leng et al., 2017). Statistically more significant reductions were seen for propiverine ER compared with tolterodine ER. Discontinuation rates because of adverse events were more in the tolterodine ER group compared with propiverine ER (7.4% vs 3.1%). Based on the way the study was designed and powered, the authors concluded that ER propiverine was noninferior to ER tolterodine (Leng et al., 2017).

Masumori et al. (2011) examined prospectively the efficacy and safety of propiverine in patients with OAB who responded poorly to previous treatment with solifenacin, tolterodine, or imidafenacin. Of 73 patients enrolled (29 men and 44 women, median age 71 years), 52 completed the protocol treatment. The OABSS was significantly improved by propiverine treatment. The scores of OAB symptoms (nighttime frequency, urgency, and urgency incontinence) except daytime frequency also improved significantly. No increase in PVR was observed. The most frequent adverse event was dry mouth (13.7%), followed by constipation (6.8%).

In a noncontrolled study in patients with wet OAB, the efficacy of propiverine on symptoms and QoL was confirmed (Komatsu et al., 2009).

Assessment.

Propiverine has a documented beneficial effect in the treatment of OAB and DO (see Table 120.3) and seems to have an acceptable side-effect profile. It

is not approved for use in the United States.

Flavoxate Hydrochloride.

Flavoxate is often discussed as a drug with mixed actions; however, its main mechanism of action may not be antimuscarinic. Flavoxate is well absorbed, and oral bioavailability appeared to be close to 100% (Guay, 2003). The drug is extensively metabolized, and plasma half-life was found to be 3.5 hours (Sheu et al., 2001). Its main metabolite (3-methylflavone-8-carboxylic acid [MFCA]) has been shown to have low pharmacologic activity (Caine et al., 1991; Cazzulani et al., 1988). **The main mechanism of flavoxate's effect on smooth muscle has not been established.** The drug has been found to possess a moderate calcium antagonistic activity, to have the ability to inhibit phosphodiesterase (PDE), and to have local anesthetic properties; no antimuscarinic effect was found (Guarneri et al., 1994).). On the other hand, Uckert et al. (2000) found that in strips of human bladder, the potency of flavoxate to reverse contraction induced by muscarinic receptor stimulation and by electrical field stimulation was comparable. It has been suggested that pertussis toxin–sensitive G proteins in the brain are involved in the flavoxate-induced suppression of the micturition reflex, because intracerebroventricularly or intrathecally administered flavoxate abolished isovolumetric rhythmic bladder contractions in anesthetized rats (Oka et al., 1996).

The clinical effects of flavoxate in patients with DO and frequency, urgency, and incontinence have been studied in both open and controlled investigations, but with varying rates of success (Ruffmann, 1988). Stanton (1973) compared emepronium bromide and flavoxate in a double-blind crossover study of patients with DO and reported improvement rates of 83% and 66% after flavoxate or emepronium bromide, respectively, both administered at 200 mg three times daily. In another double-blind crossover study comparing flavoxate 1200 mg/day with oxybutynin 15 mg/day in 41 women with idiopathic motor or sensory urgency, and using both clinical and urodynamic criteria, Milani et al. (1993) found both drugs effective. No difference in efficacy was found between them, but flavoxate had fewer and milder side effects. Other investigators comparing the effects of flavoxate with those of placebo have not been able to show any beneficial effect of flavoxate at doses up to 400 mg three times daily (Briggs et al., 1980; Chapple et al., 1990; Dahm et al., 1995). In general, few side effects have been reported during treatment with flavoxate. On the other hand, its efficacy compared with other therapeutic alternatives is not well documented in

RCTs (see Table 120.3). However, a recent meta-analysis of 43 published studies claimed to demonstrate that flavoxate had better clinical efficacy than placebo, had almost no side effects, and was worthy of consideration for the treatment of OAB (Sweeney et al., 2016). This was also a conclusion drawn by Zor et al. (2015), who suggested that flavoxate deserves more clinical studies to assess its efficacy because more studies and novel drug formulations may reveal or improve its efficacy in daily practice. Further RCTs seem to be needed to establish the place of flavoxate in the therapeutic arsenal.

Assessment.

No RCTs seem to have been performed with flavoxate during the past decade. The scarcity of evidence regarding documented clinical efficacy should be considered before use of the drug (see Table 120.3).

Key Points: Antimuscarinic Therapy

- Drugs can alter LUT function by acting at any point along the afferent or efferent limb of innervation by reception activation or blockade, by affecting the concentration of the neural transmitter at an activation site, or by stimulating or inhibiting signal transduction mechanisms. Functionally, these actions can be divided into those that facilitate bladder filling or urine storage versus those that facilitate bladder emptying or voiding. Furthermore, these actions can be subdivided into those that primarily affect the bladder or outlet. Some drugs will have an effect on both. Atropine and atropine-like agents that inhibit muscarinic receptors are the most commonly used agents to inhibit involuntary contractions. They also act to maintain low bladder tone during filling with a consequent decrease in filling and storage symptoms that are unrelated to the occurrence of an involuntary contraction. They do so primarily by the inhibition of muscarinic receptors located on detrusor muscle cells, urothelial cells, suburothelial nerves, and interstitial cells. There are five pharmacologically defined muscarinic receptors; the M_2 receptor is the most common in the human bladder, but the M_3 receptor is the most important for contraction. As opposed to the traditional view that antimuscarinics in the usual administered clinical doses act by blocking the muscarinic receptors on the detrusor muscle, they appear to act mainly during the storage phase, decreasing urgency and increasing bladder capacity. In the dosage range used for treatment of the symptoms of OAB or DO, there is little evidence for a significant reduction of the voiding contraction. Higher doses can and will produce a reduction of the voiding contraction.

- In general, drug therapy for LUT dysfunction is hindered by lack of *uroselectivity.*
- Antimuscarinics are of significant clinical benefit in the treatment of OAB and related symptoms. There are numerous such agents available, and the pharmacologic profiles of each drug and their individual characteristics differ. None, however, is ideal as a first-line treatment for all patients with OAB or DO.
- Persistence with current antimuscarinic agents for such treatment is low as a result of a combination of relative lack of efficacy and adverse effects.
- Some drugs are labeled as primarily antimuscarinic but with a mixed action, meaning there is often a poorly defined direction of action on bladder smooth muscle; however, most likely the clinical effects of such drugs can be explained primarily by the antimuscarinic action.

Drugs Acting on Membrane Channels

Calcium Antagonists.

Activation of detrusor muscle, through both muscarinic-receptor and NANC pathways, seems to require influx of extracellular Ca^{2+} through Ca^{2+} channels and via mobilization of intracellular Ca^{2+} (Andersson, 1993; Andersson and Arner, 2004)**. The influx of extracellular calcium can be blocked by calcium antagonists, blocking L-type Ca^{2+} channels, and theoretically this would be an attractive way of inhibiting DO and regulating detrusor smooth muscle tone** (Berridge, 2008)**. Two major groups of calcium channels include the voltage-gated** (Catterall et al., 2003) **and the store-operated channels** (Leung et al., 2008)**. Although both can contribute to the maintenance of smooth muscle tone in general, store-operated calcium channels apparently contribute only to a limited, if any, extent to the regulation of bladder smooth muscle tone** (Schneider et al., 2004a, 2004b). On the other hand, various types of voltage-gated calcium channels have been implicated in the regulation of bladder smooth muscle including Q-type

(Frew and Lundy, 1995) and L-type channels (Wuest et al., 2007). The latter appear to be of particular importance because inhibitors of L-type channels have repeatedly been shown to inhibit bladder contraction in vitro with tissue from multiple mammalian species, including humans (Frazier et al., 2008). However, the relative importance of L-type channels may be somewhat less in humans than in other mammalian species (Wuest et al., 2007). In confirmation of the role of L-type calcium channels, it has been shown that KO mice lacking a crucial subunit of this channel exhibit a markedly impaired bladder contractility (Wegener et al., 2004).

Although these in vitro data suggest a possible role for calcium channel inhibitors, particularly those of L-type channels, in the treatment of DO and incontinence, only limited clinical studies are available in this regard. One urodynamic study compared the effects of intravesical instillation of the calcium channel inhibitor verapamil, the muscarinic-receptor antagonists oxybutynin and trospium, and placebo in patients with urgency or urgency incontinence. Whereas the two muscarinic-receptor antagonists significantly increased bladder capacity, verapamil treatment was not associated with relevant changes in bladder function (Fröhlich et al., 1998). In a clinical study of limited size, the calcium channel inhibitor nimodipine (30 mg/day) did not significantly improve the number of incontinence episodes as compared with placebo (Naglie et al., 2002). It should be noted that despite long-standing and widespread use of calcium channel inhibitors in the treatment of cardiovascular disease, there are no major reports on impaired bladder contractility as a side effect of such treatment. The reasons for the discrepancy between the promising in vitro data and the lack of clinical data are not fully clear, but they may relate to pharmacokinetic properties of the currently used drugs, which may insufficiently either reach or penetrate bladder tissue in therapeutically administered doses. **At present, there is no clinical evidence to support a possible use of calcium channel inhibitors in the treatment of bladder dysfunction** (see Table 120.3).

Potassium Channel Openers.

Potassium channels contribute to the membrane potential of smooth muscle cells and hence to the regulation of smooth muscle tone. Numerous types of potassium channels exist in the bladder (Gutman et al., 2003; Petkov, 2011; 2014). With regard to bladder function, ATP-dependent (K_{ATP}) and big calcium-activated (BK_{Ca}) channels have been studied most intensively. The BK_{Ca} channels also appear to be important physiologically because their activation can cause hyperpolarization of bladder smooth muscle cells, and by this mechanism they can contribute to the relaxation of bladder smooth muscle by, for example, β-AR agonists (Frazier et al., 2008). Openers of both K_{ATP} (Howe et al., 1995; Hu and Kim, 1997; Martin et al., 1997) and BK_{Ca} channels (Hu and Kim, 1997; Sheldon et al., 1997) have been shown to induce bladder smooth muscle relaxation in various mammalian species, but the density of some types of potassium channels may differ markedly among species. Some potassium channel openers have also been shown to suppress nonvoiding detrusor contractions in vivo in animal models of DO (Howe et al., 1995; Martin et al., 1997; Tanaka et al., 2003), and this also includes activators of the KCNQ type of potassium channels (Streng et al., 2004). Although potassium channel openers are believed to mainly act directly on smooth muscle cells (Gopalakrishnan and Shieh, 2004; Petkov, 2011; 2014), they may also at least in part affect bladder function by modulating the activity of afferent neurons (Tanaka et al., 2003).

Although the aforementioned data demonstrate the potential of potassium channel openers to inhibit nonvoiding detrusor contractions, these channels are expressed not only in bladder, but also in, for example, vascular smooth muscle. Therefore, potassium channel openers may also affect cardiovascular function, and in effective doses may considerably lower blood pressure (Howe et al., 1995; Shieh et al., 2007). Whereas some compounds of this class have a certain degree of selectivity for the bladder as compared with the cardiovascular system, it remains unclear whether the degree of selectivity offers a sufficiently large therapeutic window for clinical use. This consideration has led to a considerable hesitancy to study potassium channel openers in OAB patients. Nevertheless, one randomized, placebo-controlled clinical study on the K_{ATP} opener ZD0947 has been reported (Chapple et al., 2006). ZD0947 at the chosen dose did not lower blood pressure or cause adverse events typical for a vasodilating drug, but it also failed to achieve superiority relative to placebo for the treatment of OAB symptoms. Therefore, **despite promising preclinical efficacy data, potassium channel openers at present are not a therapeutic option and may never become one because of a lack of selectivity for bladder over cardiovascular tissues (see Table 120.3).**

Christ et al. (2001) **suggested another way to use potassium channels to normalize bladder function was by in a rat model of detrusor hyperactivity. They injected “naked” hSlo/pcDNA3 (maxiK channel) into the bladder and found a significant amelioration of the hyperactivity. Whether this principle can be therapeutically useful in humans is currently under investigation.**

At present, there is no clinical evidence to support the possible use of potassium channel openers in the treatment of bladder dysfunction (see Table 120.3).

α-Adrenoceptor Antagonists

It is well documented that α_1-AR antagonists can ameliorate LUTS in men (Andersson, 2002b; Ishizuka et al., 2013; Lepor et al., 2012; McVary et al., 2011; Michel, 2010; Oelke et al., 2013; Yuan et al., 2013). **Currently used α_1-AR antagonists are considered effective for treatment of both storage and voiding symptoms in men with LUTS associated with or suggestive of benign prostatic hyperplasia (BPH)** (Lepor et al., 2012; Soler et al., 2013)**. However, in a study in which tamsulosin was given alone or together with tolterodine to patients with male LUTS and OAB symptoms, monotherapy with the drug was not effective** (Kaplan et al., 2006)**. Doxazosin monotherapy resulted in only minimal effects in International Prostate Symptom Score (IPSS) storage subscore and urgency episodes and no improvement in PPBC** (Lee et al., 2011).

A pivotal question is whether better efficacy and/or tolerability can be achieved by highly subtype-selective drugs than with the commonly used alternatives. **α_1-ARs include three receptor subtypes, α_{1A}, α_{1B}, and α_{1D}, that are structurally and pharmacologically distinct and have different tissue distributions** (Andersson and Gratzke, 2007; Nishimune et al., 2012; Yamada and Ito, 2011)**. α_{1A}-ARs are the predominant subtype in the human prostate,** where they mediate smooth muscle contraction. A fourth subtype, α_{1L}, also found in human prostate, is derived from the same gene as the α_{1A} subtype, but α_{1L} and α_{1A} receptors have different pharmacologic properties and bind some α-AR antagonists with different affinities. The precise structural relationship between the two subtypes remains to be elucidated. Selectivity for α_{1B}-AR has been considered disadvantageous from a cardiovascular point of view (Schwinn and Roehrborn, 2008; Schwinn et al., 2004). Kojima et al. (2008) studied the expression of α_1-AR in the transitional zone of prostates from 55 patients with BPH, comparing patients treated with tamsulosin, presumed to block α_{1A}-ARs, and naftopidil, presumed to block α_{1D}-ARs. However, the selectivity of naftopidil for α_{1D}-ARs versus α_{1A}-ARs is modest (Take et al., 1998), and its use as a tool to differentiate among α_1-AR subtypes is questionable. Nevertheless, the tamsulosin and naftopidil groups were classified as α_{1A}-AR dominant (22 and 12 patients) and α_{1D}-AR dominant (11 and 16, respectively). The efficacy of tamsulosin and naftopidil differed depending on the dominant expression of the α_1-AR subtype in the prostate. Tamsulosin was more effective in patients with dominant expression of the α_{1A}-AR subtype, whereas naftopidil was more effective in those with dominant expression of the α_{1D}-AR subtype. In another study, the same group assessed whether there was a direct correlation between the prostatic expression of α_1-AR subtype mRNA and severity of LUTS or BOO (Kojima et al., 2011). They found no direct correlation between the expression of α_1-AR subtype mRNA in the prostate and severity of LUTS or BOO, although there was a significant regression of this expression with patient age. Kojima et al. (2011) concluded that the expression level of α_1-AR subtype mRNA in the prostate could be a predictor of the efficacy of subtype-selective α_1-AR antagonists in patients with BPH and suggested that genetic differences were responsible for the diverse responses to the drugs.

Silodosin (KD-3213), which has a high selectivity for α_{1A}-ARs (Lepor and Hill, 2010; Tatemichi et al., 2006a, 2006b; Yoshida et al., 2011), had clinically good effects on both voiding and storage symptoms in men with BPH (Chapple et al., 2011; Kawabe et al., 2006; Marks et al., 2009a, 2009b; Montorsi et al., 2016; Morganroth et al., 2010; Novara et al 2013; Yoshida et al., 2007, 2011). Chapple et al. (2011) conducted a multicenter double-blind, placebo- and active-controlled parallel group study comparing silodosin, tamsulosin, and placebo. A total of 1228 men 50 years of age and older, with an IPSS of 13 or higher and a urine maximum flow rate (Qmax) greater than 4 and less than or equal to 15 mL/sec, were selected at 72 sites in 11 European countries. The patients were entered into a 2-week washout and a 4-week placebo run-in period. A total of 955 patients were randomized (2 : 2 : 1) to silodosin 8 mg ($n = 381$), tamsulosin 0.4 mg ($n = 384$), or placebo ($n = 190$) once daily for 12 weeks. Its overall efficacy was not inferior to tamsulosin. Only silodosin showed a significant effect on nocturia over placebo. There was no significant difference among the two α_1-AR antagonists and the placebo in terms of Qmax. There was also no difference between the two α-AR antagonists for the QoL parameter, although both were better than the placebo. Active treatments were well tolerated, and discontinuation rates resulting from adverse events were low in all groups (2.1%, 1.0%, and 1.6% with silodosin, tamsulosin, and placebo, respectively). The most frequent adverse event with silodosin was a reduced or absent ejaculation during orgasm (14%), a reversible effect as a consequence of the potent and selective α_{1A}-AR antagonism of the drug. The incidence was higher than that observed with tamsulosin (2%); however, only 1.3% of silodosin-treated patients discontinued treatment because of this adverse event. Silodosin treatment improved DO and obstruction grade by decreasing detrusor opening pressure, detrusor pressure at Qmax, BOO Index score, and Schafer obstruction class significantly (Yamanishi et al., 2009). In a different open, nonblinded prospective study, silodosin 8 mg led to a significant increase in bladder capacity at first desire to void with no significant change in maximum cystometric capacity. In the voiding phase, mean detrusor pressure at maximum flow significantly decreased, mean BOO Index score decreased significantly, and obstruction grade as assessed by the Schaefer nomogram improved significantly (Matsukawa et al., 2009).

It thus seems that **selective blockade of α_{1A}-ARs is a clinically effective approach,** and silodosin is an effective and well-tolerated treatment for the relief of both voiding and storage symptoms in male patients with LUTS, even if treatment is associated with a high incidence of ejaculatory dysfunction.

Interest has also been focused on the α_1-ARs (α_{1D}), specifically in the bladder (Schwinn and Roehrborn, 2008; Schwinn et al., 2004), on the assumption that these receptors were responsible for storage symptoms. However, **the interrelationship between the α_{1D}-ARs in the human detrusor smooth muscle and the pathophysiology of LUTS is unclear.** Naftopidil was shown to significantly improve the OABSS (Sakai et al., 2011) and urgency episodes (Yokoyama et al., 2009). Ikemoto et al. (2003) gave tamsulosin and naftopidil to 96 patients with BPH for 8 weeks in a crossover study. Whereas naftopidil monotherapy decreased the IPSS for storage symptoms, tamsulosin monotherapy decreased the IPSS for voiding symptoms. However, this difference (which was suggested to depend on differences in affinity for α_1-AR subtypes between the drugs) could not be reproduced in a randomized head-to-head comparison between the drugs (Gotoh et al., 2005). Based on available evidence, it therefore cannot be concluded that the α_{1D}-ARs on the detrusor smooth muscle are the main therapeutic target. However, α_{1D}-ARs may have effects on different locations in the bladder aside from the detrusor smooth muscle: the detrusor vasculature, the urothelium, and the afferent and efferent nerve terminals and intramural ganglia (Andersson and Gratzke, 2007; Moro et al., 2013; Yamada and Ito, 2011). The importance and functional role of this observation remain to be established.

In women, treatment of OAB symptoms with α_1-AR antagonists seems to be ineffective. In an RCT including 364 women with OAB, no effect of tamsulosin versus placebo could be demonstrated (Robinson et al., 2007). On the other hand, voiding symptoms in women with functional outflow obstruction or LUTS were treated (with modest success) with an α_1-AR antagonist (Kessler et al., 2006; Low et al., 2008). **It should be remembered that in women, these drugs may produce stress incontinence** (Dwyer and Teele, 1992).

In patients with NDO, treatment with α_1-AR antagonists was moderately successful (Abrams et al., 2003).

β-Adrenoceptor Agonists

Background.

The three cloned subtypes of β-ARs (β_1, β_2, and β_3) have been identified in the detrusor of most species, including humans (Andersson and Arner, 2004; Michel and Vrydag, 2006). In addition, the human urothelium contains all three receptor subtypes (Otsuka et al., 2008). Studies using real-time reverse transcription polymerase chain reaction (RT-PCR) have revealed a predominant expression of β3-AR mRNA in human detrusor muscle (Igawa et al., 2010; Michel and Vrydag, 2006; Nomiya and Yamaguchi, 2003), and the functional evidence for an important role in both normal and neurogenic bladders is convincing (Biers et al., 2006; Fujimura et al., 1999; Igawa et al., 1999, 2001, 2010; Leon et al., 2008; Michel and Vrydag, 2006; Morita et al., 2000; Takeda et al., 1999;). The human detrusor also contains β_2-ARs, and most likely both receptors are involved in the physiologic effects (relaxation) of noradrenaline (NA) in this structure (Andersson and Arner, 2004; Igawa et al., 2010; Michel and Vrydag, 2006).

The generally accepted mechanism by which β-ARs induce detrusor relaxation in most species is activation of adenylyl cyclase with the subsequent formation of cAMP. However, there is evidence suggesting that in the bladder, K^+ channels, particularly BK_{Ca} channels, may be more important in β-AR–mediated relaxation than cAMP (Frazier et al., 2005, 2008; Hudman et al., 2000; Uchida et al., 2005). However, other mechanisms of action cannot be excluded (Andersson, 2017). Stimulation of β_3-AR inhibits spontaneous contractile activity in the detrusor (in vitro: microcontractions; in vivo: nonvoiding contractions) and reduces bladder afferent activity (Aizawa et al., 2012; Biers et al., 2006; Gillespie et al., 2012; Hatanaka et al., 2013; Igawa and Michel, 2013; Takasu et al., 2007). Spontaneous contractile detrusor activity may be a source of increased afferent activity. Aizawa et al. (2012) showed that the β_3-AR agonist mirabegron could inhibit filling-induced activity in both mechanosensitive Aδ- and C-fiber primary bladder afferents of the rat bladder. Gillespie et al. suggested that effects on neither spontaneous microcontractions nor on nonvoiding contractions (e.g., in obstructed rats) can fully explain the effects of mirabegron (Eastham and Gillespie, 2013; Gillespie et al., 2015a,b; Granato et al., 2015). Assuming that spontaneous release of ACh from cholinergic terminals during bladder filling stimulates spontaneous contractile activity, the finding that activation of prejunctional β_3-ARs may downregulate ACh release may be of importance (Andersson, 2017; D'Agostino et al., 2015; Rouget et al., 2014).

Because β-ARs are present in the urothelium, their possible role in bladder relaxation has been investigated (Murakami et al., 2007; Otsuka et al., 2008). However, to what extent a urothelial signaling pathway contributes in vitro and in vivo to the relaxant effects of β-AR agonists in general, and β_3-AR agonists specifically, remains to be elucidated.

The in vivo effects of β_3-AR agonists on bladder function have been studied in several animal models. It has been shown that compared with other agents (including antimuscarinics**)**, **β_3-AR agonists increase bladder capacity with no change in micturition pressure and the residual volume** (Fujimura et al., 1999; Igawa et al., 2010; Kaidoh et al., 2002; Takeda et al., 2002; Woods et al., 2001). For example, Hicks et al. (2007) studied the effects of the selective β_3-AR agonist GW427353 in the anesthetized dog and found that the drug evoked an increase in bladder capacity under conditions of acid-evoked bladder hyperactivity, without affecting voiding.

There have been some reports that β_3-AR agonists (e.g., mirabegron) may have effects that are off-target (Dehvari et al., 2018) or not related to β_3-AR stimulation (e.g., relaxing effects on urethral α-ARs) (Alexandre et al., 2016) or non–β_3-AR–mediated cardiac effects (Mo et al., 2017). However, it seems unlikely that these pharmacologic effects demonstrated in vitro have any clinical relevance (Andersson 2016; 2017).

Clinical Use.

The selective β_3-AR agonist mirabegron has been approved for treatment of OAB in Japan (Betanis), the United States (Myrbetriq), and Europe (Betmiga), and its properties and clinical effects have been extensively reviewed (Andersson et al., 2013b; Bridgeman et al., 2013; Chapple et al., 2014b; Sacco and Bientinesi, 2012; Sebastianelli et al., 2018). There are proof-of-concept studies for other β_3-AR selective agonists such as solabegron and ritobegron (Igawa and Michel, 2013, see later). However, the development of ritobegron has been ceased because it failed to reach the primary efficacy end point in phase III studies.

Mirabegron

Pharmacokinetics.

Mirabegron is **rapidly absorbed** after oral administration. It circulates in the plasma as the unchanged form, its glucuronic acid conjugates and other metabolites, **the metabolites being inactive** (Takusagawa et al., 2012b). Of the administered dose, **55% is excreted in urine, mainly as the unchanged form, and 34% is recovered in feces,** almost entirely as the unchanged form. **Mirabegron is highly lipophilic and is metabolized in the liver via multiple pathways,** mainly by cytochrome P450 3A4 and 2D6 (CYP3A4, CYP2D6) (Takusagawa et al., 2012a,c). It may therefore be subject to clinically relevant drug-drug interactions and should be used with caution in patients who are taking ketoconazole or other potent CYP3A4 inhibitors.

Tmax in both extensive and poor metabolizers was about 2 hours, and the terminal elimination half-life was approximately 23 to 25 hours (Eltink et al., 2012; Krauwinkel et al., 2012).

Efficacy.

Several phase II RCTs have shown that in OAB patients mirabegron consistently improved mean number of micturitions in 24 hours and number of continence episodes in 24 hours (Chapple et al., 2013a, 2013b, 2013c). Mirabegron was further evaluated in three pivotal phase III, 12-week RCTs in patients with OAB symptoms of UUI, urgency, and urinary frequency (Herschorn et al., 2013; Khullar et al., 2013; Nitti et al., 2013a). These trials had basically similar design. Entry criteria required that patients had symptoms of OAB for at least 3 months' duration, at least eight micturitions per day, and at least three episodes of urgency with or without incontinence over a 3-day period. The majority of patients were Caucasian (94%) and female (72%), with a mean age of 59 years (range 18 to 95 years).

In the study by Nitti et al. (2013a), 1329 patients were randomized to receive placebo or mirabegron 50 or 100 mg once daily for 12 weeks. **Coprimary end points were change from baseline to final visit (study end) in the mean number of incontinence episodes per 24 hours and micturitions per 24 hours.** At the final visit, mirabegron 50 and 100 mg showed **statistically significant improvements in the coprimary efficacy end points and MVV per micturition compared with placebo.**

Khullar et al. (2013) performed a similarly designed study enrolling 1978 patients. The study included a fourth arm in which tolterodine SR 4 mg was used as a comparator. As in the study by Nitti et al. (2013a), it was found that mirabegron caused a statistically significant improvement from baseline compared with placebo in the number of urgency incontinence episodes and number of micturitions per 24 hours. Mirabegron 50 and 100 mg were statistically superior to placebo, whereas tolterodine was not, in these two key OAB symptoms, but the study was not powered for head-to-head evaluation.

In a third phase III study in which Herschorn et al. (2013) evaluated the effects of 25 and 50 mg of mirabegron, both doses were associated with significant improvements in efficacy measures of incontinence episodes and micturition frequency.

Nitti et al. (2013c) reported on the effects of mirabegron on maximum urinary flow rate and detrusor pressure at maximum flow rate in a urodynamic safety study on male patients with BOO and LUTS. Two hundred men with OAB symptoms and a BOO Index score above 20 were randomized to receive placebo, mirabegron 50 mg, or mirabegron 100 mg once daily for 12 weeks. Mirabegron did not adversely affect flow rate, detrusor pressure at maximum flow rate, or bladder contractile index and was well tolerated.

Otsuki et al. (2013) reported on the efficacy and safety of mirabegron in a predominantly male population of OAB patients. In this prospective, nonrandomized, controlled study, patients with at least one episode of urgency per week and scoring at least 2 for urinary urgency in the OABSS were enrolled. Fifty-two patients (36 men) with newly diagnosed OAB received mirabegron 50 mg once daily; 45 patients (36 men) with OAB refractory to antimuscarinics switched to mirabegron; and another 27 patients (18 men) with newly diagnosed

OAB received antimuscarinics and served as controls. Patients on a stable α_1-AR blocker dose for treatment of LUTS were allowed in the study, but those with a PVR greater than 100 mL were excluded. Mirabegron achieved significant improvements in all efficacy outcomes (OABSS and IPSS). In patients with newly diagnosed OAB, improvements were not significantly different to those achieved by antimuscarinics. Mirabegron was well tolerated and did not significantly change PVRs. However, these encouraging results for mirabegron in treating male OAB should be interpreted with caution in view of the limitations of the study, which included small patient numbers, lack of randomization, and a suboptimal treatment period for the indication.

In a study by Chapple et al. (2013c) assessing the 12-month safety and efficacy of mirabegron, tolterodine was used as an active control. There were no significant differences in efficacy between drugs. However, whether mirabegron has similar efficacy to antimuscarinics awaits direct comparison studies. Mirabegron seems to have definite advantages over the antimuscarinics with respect to adverse events. Dry mouth and constipation are essentially nonexistent in comparison to placebo (Chapple et al., 2013a, 2013b, 2013c, 2014; Cui et al., 2014; Rossanese et al., 2015).

Mirabegron 50 mg and solifenacin 5 mg were recently compared in OAB patients who were dissatisfied with previous antimuscarinic treatment. The BEYOND study (Batista et al., 2015) was a randomized, double-blind, phase IIIb, noninferiority study that enrolled male and female patients 18 years of age and older, with symptoms of OAB for 3 months or longer, who were dissatisfied with their previous antimuscarinic drug because of lack of efficacy.

Tolerability and Adverse Effects.

In a proof-of-concept study of mirabegron 100 and 150 mg bid (Chapple et al., 2013a)**, adverse events were experienced by 45.2% of the patients—the incidence was similar among those treated with placebo (43.2%) and mirabegron (43.8% to 47.9%). The most commonly reported adverse events considered to be treatment related were gastrointestinal disorders,** including constipation, dry mouth, dyspepsia, and nausea. There was **no patient-reported acute retention.** No significant difference in ECG parameters between the groups was demonstrated. However**, a small but significant increase in mean pulse rate was observed after mirabegron 100 mg and 150 mg (1.6 and 4.1 beats/min, respectively), although this was not associated with an increase in cardiovascular adverse events in this study.** The overall discontinuation rate resulting from adverse events was 3.2% (placebo 3.0% vs. mirabegron 2.4% to 5.3%).

In the study by Khullar et al. (2013), the incidence of adverse effects was similar across the placebo and mirabegron 50- and 100-mg groups (50.1%, 51.6%, and 46.9%, respectively). The most common (≥3%) adverse effects in any treatment group were hypertension (6.6%, 6.1%, and 4.9%, respectively), urinary tract infection (1.8%, 2.7%, and 3.7%), headache (2.0%, 3.2%, and 3.0%), and nasopharyngitis (2.9%, 3.4%, and 2.5%). The incidence of dry mouth was similar in the placebo and mirabegron groups (2.6% vs. 2.8%) and lower than observed in patients receiving tolterodine SR (10.1%). The incidence of constipation was similar in all treatment groups (placebo, 1.4%; mirabegron, 1.6%), including tolterodine (2.0%).

In the **12-month safety and efficacy study** of mirabegron referred to previously, the incidence and severity of treatment-emergent and serious adverse effects (primary outcome parameters) were similar across the mirabegron 50-mg (59.7%), mirabegron 100-mg (61.3%), and tolterodine SR 4-mg (62.6%) groups (Chapple et al., 2013c). **The most frequent treatment-emergent adverse events (TEAEs) were hypertension, constipation, and headache,** which occurred at a similar incidence across all treatment groups; the incidence of dry mouth was more than threefold lower compared with the tolterodine SR 4-mg group (Chapple et al., 2013c).

One concern with the use of β_3-AR agonists has been the possibility of negative cardiovascular effects. In healthy subjects, mirabegron (50 to 300 mg/day for 10 days) increased **blood pressure** in a dose-dependent manner (Mirabegron prescribing information, 2012). However, in the studies on OAB patients, the mean increase (compared with placebo) in systolic and diastolic blood pressure after therapeutic doses of mirabegron once daily was approximately 0.5 to 1 mm Hg and was reversible on discontinuation of treatment.

In a study of healthy volunteers, mirabegron increased HR and systolic blood pressure and reduced stroke volume, whereas cardiac output and diastolic blood pressure were unaffected (van Gelderen et al., 2017). The data indicated that mirabegron has a positive chronotropic effect at supratherapeutic concentrations, which is at least partly mediated by stimulation of β_1-AR.

Mirabegron increased HR in a dose-dependent manner. Maximum mean increases in HR from baseline for the 50-mg, 100-mg, and 200-mg dose groups compared with placebo were 6.7 beats/min, 11 beats/min, and 17 beats/min, respectively (van Gelderen et al., 2017). However, in the clinical efficacy and safety studies, the change from baseline in mean pulse rate for mirabegron 50 mg was approximately 1 beat/min and reversible on discontinuation of treatment.

The cardiac safety of mirabegron was evaluated in a thorough QT/QTc (HR-corrected QT interval) study, including supratherapeutic dose. This was a randomized, placebo- and active- controlled (moxifloxacin 400 mg), four–treatment-arm, parallel crossover study (Malik et al., 2012), and the design followed the recommendations of the International Conference on Harmonisation (ICH). Equal numbers of men and women were enrolled in each treatment group, and the pharmacokinetic and pharmacodynamic analyses included 333 and 317 subjects, respectively. The effect of multiple doses of mirabegron 50 mg, 100 mg, and 200 mg once daily on QTc interval was studied, and according to ICH E14 criteria, mirabegron **did not cause QTcI prolongation at the 50-mg therapeutic and 100-mg supratherapeutic doses in patients of either sex**. Mirabegron prolonged QTcI interval at the 200-mg supratherapeutic dose (upper one-sided 95% CI >10 msec) in women, but not in men.

Even if the cardiovascular effects of mirabegron observed in clinical studies have been minimal and clinically not relevant, effects on HR and blood pressure need to be monitored when the drug is prescribed and patients with cardiovascular morbidities are treated.

New Developments

Thiagamoorthy et al. (2015) reviewed “novel and putative” β_3-AR agonists for management of OAB, including CL-316243, TRK-380, AJ-9677, and BRL37344. Another agent, vibegron, was claimed to have an overall superior preclinical profile compared with MK-0634, which was discontinued because of unacceptable structure-based toxicity in preclinical species (Edmonson et al., 2016). Vibegron is a potent, selective full β_3-AR agonist across species, and it dose-dependently increased bladder capacity, decreased micturition pressure, and increased bladder compliance in rhesus monkeys (Di Salvo et al., 2017). The relaxation effect of vibegron was enhanced when combined with muscarinic antagonists, but differentially influenced by muscarinic receptor subtype selectivity. The effect was greater when vibegron was coadministered with tolterodine, a nonselective antagonist, compared with coadministration with darifenacin, a selective M_3-receptor antagonist. Furthermore, a synergistic effect for bladder strip relaxation was observed with the combination of a β_3-AR agonist and tolterodine in contrast with simple additivity with darifenacin. The authors speculated that a combination of β_3-AR agonists with M_2/M_3 antimuscarinics has the potential to redefine the standard of care for the pharmacologic treatment of overactive bladder. Even if these agents have been reported as being in development, no clinical data have been published, and it may be questioned whether any of them can be regarded as “novel and putative.” Phase II and III randomized, double blind, placebo-controlled studies of ritobegron in patients with OAB have been initiated and completed, but the results have not been published, and it seems that that the primary efficacy end point of the studies was not met. No new clinical trials with ritobegron seem to have been initiated.

Efficacy and safety of solabegron (GW427353) have been reported in a phase II multicenter, randomized, proof-of-concept trial in 258 women with wet OAB. The drug produced a statistically significant difference in percent change from baseline to week 8 in incontinence episodes over 24 h (primary outcome) when compared with placebo ($P = 0.025$) and was well tolerated (Ohlstein et al., 2012).

There seems to be a number of β_3-AR agonists in the pipeline, some of which are under development. However, it is uncertain which, if any, will come to market and be available for the management of OAB.

Phosphodiesterase Inhibitors

Drugs stimulating the generation of cAMP are known to relax smooth muscles, including the detrusor (Andersson and Wein, 2004; Andersson et al., 1999)**. It is also well established that drugs acting through the nitric oxide (NO)/cyclic guanosine monophosphate (cGMP) system can relax the smooth muscle of the bladder outflow region** (Andersson and Arner, 2004)**. Use of PDE inhibitors to enhance the presumed cAMP- and cGMP-mediated relaxation of LUT smooth muscles (detrusor, prostate, urethra) should then be a logical approach** (Andersson, 2011c; Andersson et al., 2007; Ückert et al., 2013). There are presently 11 families of PDEs, some of which preferentially hydrolyze either cAMP or cGMP (Rahnama'i et al., 2013; Uckert et al., 2006).

As a basis for PDE inhibitor treatment of LUTS, Uckert et al. (2006) investigated human bladder tissue, revealing mRNA for PDE types 1A, 1B, 2A, 4A, 4B, 5A, 7A, 8A, and 9A; most of these PDE types preferably inhibit the breakdown of cAMP. In vitro, human detrusor muscle responded poorly to sodium nitroprusside and to agents acting via the cGMP system (Truss et al., 2000). However, significant relaxation of human detrusor muscle, paralleled by increases in cyclic nucleotide levels, was induced by papaverine, vinpocetine (a low-affinity inhibitor of PDE type 1 [PDE1]), and forskolin (stimulating the generation of cAMP), suggesting that the cAMP pathway and PDE1 may be important in regulation of detrusor smooth muscle tone (Truss et al., 2001). Significant dose-dependent relaxations were also induced by human cAMP analogues (Truss et al., 2001). With these studies as a background, Truss et al. (2000) presented preliminary clinical data for vinpocetine in patients with urgency and urgency incontinence or low-compliance bladders who were not responding to standard antimuscarinic therapy. This initial open pilot study suggested a possible role for vinpocetine in the treatment of OAB. However, the results of a larger RCT in patients with DO showed that vinpocetine only showed statistically significant results for one parameter (Truss et al., 2001). Studies with PDE1 inhibitors other than vinpocetine (which may not be an optimal drug for elucidation of the principle) do not seem to have been performed.

PDE4 (which also preferably hydrolyzes cAMP) has been implicated in the control of bladder smooth muscle tone. PDE4 inhibitors reduced the in vitro contractile response of guinea pig (Longhurst et al., 1997) and rat (Kaiho et al.,

2008) bladder strips and also suppressed rhythmic bladder contractions of the isolated guinea pig and rat bladder (Gillespie and Drake, 2004; Nishiguchi et al., 2007). Previous experiences with selective PDE4 inhibitors showed emesis to be a dose-limiting effect (Giembycz, 2005). If this side action can be avoided, PDE4 inhibition seems to be a promising approach.

Oger et al. showed that the PDE5 inhibitor sildenafil–induced relaxation of human detrusor smooth muscle involved cGMP-, cAMP- and K^+ channel–dependent signaling pathways, with a minor contribution from NO (Oger et al., 2010). In combination with the α_1-AR antagonist doxazosin, sildenafil reduced adrenergic tone of prostatic and cavernosal smooth muscle, and their combination provided a significant benefit when targeting relaxation of both tissues (Oger et al., 2008).

In vivo, several studies have indicated a role for PDE5 inhibitors in the regulation of micturition function. Systemic vardenafil reduced both nonvoiding contractions and bladder afferent nerve firing in unanesthetized, decerebrate, spinal cord–injured rats, indicating potential mechanisms by which PDE5 inhibitors improve storage symptoms in SCI patients (Behr-Roussel et al., 2010). The effect of vardenafil on OAB symptoms could be related to a cGMP-dependent RhoA/ROCK signaling inhibition, as shown in spontaneously hypertensive rats (Morelli et al., 2009a, 2009b). Using the same animal model, bladder hypoxia was significantly reduced by acute vardenafil treatment (Morelli et al., 2009b). Thus, in addition to relaxing muscular wall, PDE5 inhibition may positively affect urinary bladder blood perfusion. In the same respect, tadalafil was shown to increase prostate tissue oxygenation in spontaneously hypertensive rats, and human vesicular-deferential artery is characterized by a high expression and activity of PDE5, which was inhibited by tadalafil in vitro; these results suggest another possible mechanism through which PDE5 inhibitors exert beneficial effects on LUTS (Morelli et al., 2011).

NO has been demonstrated to be an important inhibitory neurotransmitter in the smooth muscle of the urethra, and its relaxant effect is associated with increased levels of cGMP (Andersson and Arner, 2004). However, few investigations have addressed the cAMP- and cGMP-mediated signal transduction pathways and the key enzymes of the cGMP system in the mammalian urethra. Morita et al. (1994) examined the effects of isoproterenol, prostaglandin E_1 (PGE_1), and PGE_2, and sodium nitroprusside on the contractile force and tissue content of cAMP and cGMP in the rabbit urethra. They concluded that both cyclic nucleotides can produce relaxation of the urethra.

Werkström et al. (2006) characterized the distribution of PDE5, cGMP, and protein kinase PKG1 in female pig and human urethra and evaluated the effect of pharmacologic inhibition of PDE5 in isolated smooth muscle preparations. After stimulation with the NO donor, DETA NONOate, the cGMP immunoreactivity in urethral and vascular smooth muscles increased. There was a wide distribution of cGMP- and vimentin-positive interstitial cells between pig urethral smooth muscle bundles. PDE5 immunoreactivity could be demonstrated within the urethral and vascular smooth muscle cells, but also in vascular endothelial cells that expressed cGMP immunoreactivity. Nerve-induced relaxations of urethral preparations were enhanced at low concentrations of sildenafil, vardenafil, and tadalafil, whereas there were direct smooth muscle relaxant actions of the PDE5 inhibitors at high concentrations. Fibbi et al. (2009) confirmed that the highest expression and biologic activity of PDE5 was found in the bladder. However, consistent PDE5 expression and activity were also found in prostatic urethra. In contrast, the prostate gland showed the lowest PDE5 abundance, and cultures derived from this tissue were less sensitive to vardenafil. Using a different animal model associated with C-fiber afferent activation, it was shown that the NO/cGMP signaling pathway is involved in the regulation of the micturition reflex, with an action that seems more predominant on the sensory rather than on the motor component of the micturition reflex (Caremel et al., 2010).

The observation that patients treated for erectile dysfunction (ED) with PDE5 inhibitors had an improvement of their LUTS has sparked a new interest in using these drugs also for treatment of LUTS and OAB. After the report in an open study that treatment with sildenafil appeared to improve urinary symptom scores in men with ED and LUTS (Sairam et al., 2002), this observation has been confirmed in several well-designed and well-conducted RCTs.

To date, several RCTs have been published comparing the effect of PDE5 inhibitors alone with placebo, and the combination of α_1-AR antagonists and PDE5 inhibitors versus α_1-AR antagonists alone (Andersson et al., 2017; Bechara et al., 2008; Gacci et al., 2012, 2016; Kaplan et al., 2007; Liguori et al., 2009; McVary et al., 2007a, 2007b; Porst et al., 2009, 2011; Roehrborn et al., 2008b; Stief et al., 2008; Tamimi et al., 2010; Tuncel et al., 2010). In these studies, different PDE5 inhibitors and different doses were administered.

PDE5 inhibitors significantly improve IPSS and International Index of Erectile Function (IIEF) scores, but not Qmax, when compared with placebo. According to a recent meta-analysis by Gacci et al. (2012), differences in IPSS score were significantly lower in older and obese patients. The combination of PDE5 inhibitors and α-blockers led to significant improvements in IPSS and IIEF scores and in Qmax when compared with the use of α-blockers alone. Dmochowski showed that tadalafil once daily for LUTS had no significant effect on bladder function as measured by detrusor pressure at maximum urinary flow rate or maximum detrusor pressure and BOO Index score while improving IPSS (Dmochowski et al., 2010b). PDE5 inhibitors were shown to be generally safe and well tolerated.

The mechanism behind the beneficial effect of the PDE inhibitors on LUTS and OAB and their site(s) of action largely remain to be elucidated (Andersson et al., 2011b; Giuliano et al., 2013). If the site of action were the smooth muscles of the outflow region (and the effect relaxation), an increase in flow rate should be expected. No such effect was found in urodynamic studies (Dmochowski et al., 2010b, 2013). However, there are several other structures in the LUT that may be involved, including those in the urothelial signaling pathway (urothelium, interstitial cells, and suburothelial afferent nerves). In general, it is believed that major mechanisms contributing to LUTS include reduced NO/cGMP signaling pathway, increased RhoA-kinase pathway activity, autonomic overactivity, increased bladder afferent activity, and pelvic ischemia (Andersson et al., 2011b). Nomiya et al. (2013) found in a rat model of chronic bladder ischemia that tadalafil had a marked protective effect, preventing both functional and morphologic bladder changes induced by progressive ischemia. This is in line with the proposal by Cellek et al. (2013) linking the effectiveness of PDE5 inhibitors on BPH and LUTS (and ED) to microvascular dysfunction within the pelvic organs. They suggested that a combination of endothelial and neural dysfunction may lead to a vicious cycle of hypoxia, vasoconstriction, altered smooth muscle contractility, and degeneration of autonomic neurons and ganglia.

It has to be mentioned that **as of the time of this writing, only tadalafil has been approved for the treatment of LUTS caused by benign prostatic obstruction (BPO);** long-term experience with PDE5 inhibitors in patients with LUTS is still lacking (Oelke et al., 2014). In addition, insufficient information is available on the combination of PDE5 inhibitors with other LUTS medications such as 5α-reductase inhibitors.

Antidepressants

Some clinicians believe that tricyclic antidepressants, particularly

imipramine (Tofranil, others), are useful agents for facilitating urine storage, both by decreasing bladder contractility and increasing outlet resistance (Wein, 1995a, 1995b). These agents have been the subject of a voluminous amount of highly sophisticated pharmacologic investigation to determine the mechanisms of action responsible for their varied effects (Baldessarini, 2006; Maggi et al., 1989a; Richelson, 1994). Most data have been accumulated as a result of trying to explain the antidepressant properties of these agents and are thus primarily from CNS tissue. The results, conclusions, and speculations inferred from the data are extremely interesting, but it should be emphasized that it is essentially unknown whether they apply to or have relevance for the LUT.

Tricyclic antidepressants possess varying degrees of at least three major pharmacologic actions: (1) They have central and peripheral antimuscarinic effects at some, but not all, sites; (2) they block the active transport system in the presynaptic nerve ending that is responsible for the reuptake of the released amine neurotransmitters norepinephrine and serotonin; and (3) they are sedatives, an action that occurs presumably on a central basis but is perhaps related to antihistaminic properties (at H_1 receptors, although they also antagonize H_2 receptors to some extent). There is also evidence that they desensitize at least some α_2- and some β-ARs. Paradoxically, they also have been shown to block some α-ARs and 5-HT_1 receptors.

Several antidepressants have been reported to have beneficial effects in patients with DO (Lose et al., 1989; Martin and Schiff, 1984). **However, the use of antidepressants was shown to be an independent risk factor for LUTS suggestive of BPH in a community-based population of healthy aging men** (Kok et al., 2009). In a prospective trial, and in total, 205 consecutive female patients (113 patients taking antidepressants for various disorders and 92 healthy controls), Albayrak et al. (2015) found that the prevalence of OAB was significantly higher in antidepressant users (64%) than in the control group (33%) ($P = 0.003$). They suggested that because each SSRI and SNRI has a unique pharmacologic profile, this could explain the opposing reports in the literature.

Imipramine.

Imipramine is the only drug that has been widely used clinically to treat storage symptoms. Imipramine has complex pharmacologic effects, including marked systemic antimuscarinic actions (Baldessarini, 2006) and blockade of the reuptake of serotonin and noradrenaline (Maggi et al., 1989b), but its mode of action in DO has not been established (Hunsballe and Djurhuus, 2001). **Even if it is considered that imipramine is a useful drug in the treatment of DO, no good-quality RCTs that can document this have been retrieved.** It has been known for a long time that imipramine can have favorable effects in the treatment of nocturnal enuresis in children, with a success rate of 10% to 70% in controlled trials (Glazener et al., 2003; Hunsballe and Djurhuus, 2001). It is well established that therapeutic doses of tricyclic antidepressants, including imipramine, may cause serious toxic effects on the cardiovascular system (orthostatic hypotension, ventricular arrhythmias). Imipramine prolongs QTc intervals and has an antiarrhythmic (and proarrhythmic) effect similar to that of quinidine (Bigger et al., 1977; Giardina et al., 1979). Children seem particularly sensitive to the cardiotoxic action of tricyclic antidepressants (Baldessarini, 2006). The risks and benefits of imipramine in the treatment of voiding disorders do not seem to have been assessed. Very few studies have been performed during the past decade (Hunsballe and Djurhuus, 2001; Natalin et al., 2009). No good-quality RCTs have documented that the drug is effective in the treatment of DO. However, a beneficial effect has been documented in the treatment of nocturnal enuresis.

A prospective (no controls) study of the impact of the “three-drug therapy” (antimuscarinic, α-blocker, and tricyclic antidepressants) on refractory DO showed a significant increase in bladder capacity and decreases in urgency, urgency incontinence, and frequency. Objective urodynamic data and symptom score improved significantly with triple therapy (Natalin et al., 2009).

In a retrospective study, Hillelsohn et al. (2014) evaluated 43 patients who were treated with desipramine for OAB refractory to antimuscarinic therapy. Twelve patients (28%) discontinued desipramine, 9 because of perceived lack of efficacy. Still, the authors concluded that desipramine is a potential useful treatment for patients with OAB symptoms (e.g., those with pain). To confirm any useful effect of desipramine, RCTs are needed.

Doxepin.

Doxepin is another tricyclic antidepressant that was found to be more potent, using in vitro rabbit bladder strips, than other tricyclic compounds with respect to antimuscarinic and musculotropic relaxant activity (Levin and Wein, 1984). In a randomized, double-blind crossover study of women with involuntary bladder contractions and frequency, urgency, or urgency incontinence, Lose et al. (1989) found that this agent caused a significant decrease in urine loss (pad-weighing test) and in the cystometric parameters of first sensation and maximal bladder capacity. The dose of doxepin used was either a single 50-mg bedtime dose or this dose plus an additional 25 mg in the morning. The number of daytime incontinence episodes decreased in both doxepin and placebo groups, and the difference was not statistically significant. Doxepin treatment was preferred by 14 patients, whereas 2 preferred placebo. Three patients had no preference. Of the 14 patients who stated a preference for doxepin, 12 claimed that they became continent during treatment, whereas 2 claimed improvement; the 2 patients who preferred placebo claimed improvement. The Agency for Health Care Policy and Research (AHCPR) guidelines combine results for imipramine and doxepin, citing only three RCTs, with an unknown percent of female patients. Percent cures (all figures refer to percent drug effect minus percent effect on placebo) are listed as 31%, percent reduction in urgency incontinence as 20% to 77%, and percent side effects as 0% to 70% (AHCPR, 1992).

Milnacipran Hydrochloride and Paroxetine Hydrochloride.

Milnacipran hydrochloride, a serotonin-norepinephrine reuptake inhibitor (SNRI), and *paroxetine hydrochloride,* a selective serotonin reuptake inhibitor (SSRI), were analyzed in a prospective open trial in neurogenic OAB patients (Sakakibara et al., 2008). Milnacipran reduced daytime urinary frequency, improved the QoL index score, and increased bladder capacity as shown in urodynamic studies. No such changes were noted in the other categories of the LUTS questionnaire or urodynamic studies, or in the paroxetine group.

Duloxetine.

Duloxetine is a noradrenaline-serotonin reuptake inhibitor that has been shown to significantly increase sphincteric muscle activity during the filling and storage phase of micturition in the cat acetic acid model of irritated bladder function (Katofiasc et al., 2002; Thor and Katofiasc, 1995). **Bladder capacity was also increased in this model,** with both effects mediated centrally through both motor efferent and sensory afferent modulation (Fraser et al., 2003). The effects of duloxetine were studied in a placebo-controlled trial of 306 women (21 to 84 years of age) with OAB who were randomly treated with placebo (153) or duloxetine (80 mg/day for 4 weeks, which was increased to 120 mg/day for 8 weeks) (Steers et al., 2007). The primary efficacy analysis compared the treatment effects on mean change from baseline to end point in the mean number of voiding episodes per 24 hours. **Patients randomized to duloxetine had significant improvements over those randomized to placebo for decreases in voiding and incontinence episodes (−1.81 vs. −0.62), for increases in daytime voiding intervals (29 vs. 7 minutes), and for improvements in Incontinence Quality of Life (I-QoL) scores at both doses of duloxetine.** Urodynamic studies showed no significant increases in maximum cystometric capacity or in the volume threshold for DO. The most common TEAEs with duloxetine (nausea 31% [placebo 4.6%], dry mouth 16% [placebo 1.3%], dizziness 14% [placebo 0.7%], constipation 14% [placebo 3.3%], insomnia 13% [placebo 1.3%], and fatigue 11% [placebo 2.0%]) were the same as those reported by women with stress urinary incontinence (SUI) (see later) and were significantly more common with duloxetine than placebo. Also, in women with mixed incontinence, improvement of the OAB component has been demonstrated (Bent et al., 2008; Schagen van Leeuwen et al., 2008). For assessment, see Table 120.3.

Side Effects and Cardiovascular Risks.

With the typically larger doses used for antidepressant effects, **the most frequent side effects of the tricyclic antidepressants are those attributable to their systemic antimuscarinic activity** (Baldessarini, 2006; Richelson, 1994). Allergic phenomena, including rash, hepatic dysfunction, obstructive jaundice, and agranulocytosis may also occur, but rarely. CNS side effects may include weakness, fatigue, Parkinsonian effect, a fine tremor noted mostly in the upper extremities, a manic or schizophrenic picture, and sedation, probably from an antihistaminic effect. Postural hypotension may also be seen, presumably on the basis of selective blockade (a paradoxic effect) of α_1-ARs in some vascular smooth muscle. Tricyclic antidepressants can also cause excess sweating of obscure cause and a delay of orgasm or orgasmic impotence, the cause of which is likewise unclear. They can also produce arrhythmias and interact in deleterious ways with other drugs, so caution must be observed in their use in patients with cardiac disease (Baldessarini, 2006). Whether cardiotoxicity will prove to be a legitimate concern in patients receiving the smaller doses (than for treatment of depression) for LUT dysfunction remains to be seen but is a potential matter of concern. Consultation with a patient's internist or cardiologist is always helpful before instituting such therapy in questionable situations. It is well established that **therapeutic doses of tricyclic antidepressants, including**

imipramine, may cause serious toxic effects on the cardiovascular system (orthostatic hypotension, ventricular arrhythmias). Imipramine prolongs QTc intervals and has an antiarrhythmic (and proarrhythmic) effect similar to that of quinidine (Bigger et al., 1977; Giardina et al., 1979). Children seem particularly sensitive to the cardiotoxic action of tricyclic antidepressants (Baldessarini, 2006).

With respect to the potential cardiovascular risks of antidepressant medication, two additional points need to be made. First of all, it may be depression itself that is associated with an increased risk for myocardial infarction, cardiovascular disease, and all-cause mortality (see references in Cohen et al., 2000). Although treatments for depression, including antidepressive medications, are certainly a potential factor underlying this association, the separation from disease association and treatment association is difficult at best. The second point relates to whether there is a difference in this regard between the use of tricyclic antidepressants and SSRIs. Data presented by Cohen et al. suggest that with respect to long-term adverse cardiovascular outcome, there is an association between the use of tricyclic antidepressants but not SSRIs, a conclusion that differs from earlier data, indicating no significant differences in the safety or efficacy of these two groups of agents (AHCPR report, cited by Cohen et al., 2000). As a closing statement on this subject, it should be noted that data in the literature refer to therapeutic doses of these medications for depression and not the smaller (in comparison) doses of imipramine used for the treatment of voiding dysfunction.

The use of imipramine is contraindicated in patients receiving monoamine oxidase inhibitors, because severe CNS toxicity can be precipitated, including hyperpyrexia, seizures, and coma. Some potential side effects of the antidepressants may be especially significant for the elderly, specifically weakness, fatigue, and postural hypotension. Psychotropic drugs in general have been shown to increase the risk for falls and hip fractures in the elderly (Liu et al., 1998). If imipramine or any of the tricyclic antidepressants is to be prescribed for the treatment of voiding dysfunction, the patient should be thoroughly informed of the fact that this is not the usual indication for this drug and that potential side effects exist. Reports of significant side effects (severe abdominal distress, nausea, vomiting, headache, lethargy, and irritability) after abrupt cessation of high doses of imipramine in children would suggest that the drug should be discontinued gradually, especially in patients receiving high doses.

Cyclooxygenase Inhibitors

Human bladder mucosa has the ability to synthesize eicosanoids (Jeremy et al., 1987), and these agents can be liberated from bladder muscle and mucosa in response to different types of trauma (Downie and Karmazyn, 1984; Leslie et al., 1984). Even if prostaglandins cause contraction of human detrusor (Andersson, 1993), **it is still unclear whether prostaglandins contribute to the pathogenesis of DO. More important than direct effects on the bladder muscle may be sensitization of sensory afferent nerves, increasing the afferent input produced by a given degree of bladder filling.** Involuntary bladder contractions can then be triggered at a small bladder volume. If this is an important mechanism, treatment with prostaglandin synthesis inhibitors could be expected to be effective. However, **clinical evidence for this is scarce.**

Cardozo et al. (1980) performed a double-blind, controlled study of 30 women with DO using the prostaglandin synthesis inhibitor flurbiprofen at a dose of 50 mg three times daily. The drug was shown to have favorable effects, although it did not completely abolish DO. There was a high incidence of side effects (43%) including nausea, vomiting, headache, and gastrointestinal symptoms. Palmer (1983) studied the effects of flurbiprofen 50 mg × 4 versus placebo in a double-blind crossover trial in 37 patients with IDO (27% of the patients did not complete the trial). Active treatment significantly increased maximum contractile pressure, decreased the number of voids, and decreased the number of urgent voids compared with baseline. Indomethacin 50 to 100 mg daily was reported to give symptomatic relief in patients with DO compared with bromocriptine in a randomized, single-blind crossover study (Cardozo and Stanton, 1980). The incidence of side effects was high, occurring in 19 of 32 patients. However, no patient had to stop treatment because of side effects.

The few controlled clinical trials on the effects of prostaglandin synthesis inhibitors in the treatment of DO, and the limited number of drugs tested, makes it difficult to evaluate their therapeutic value. No new RCTs on the effects of cyclooxygenase (COX) inhibitors in OAB and DO patients seem to have been published during the past decade.

Although these early clinical studies with nonselective COX inhibitors showed some promise in the treatment of these disorders, the drugs were not further developed for this indication, mainly because of side effects. The interest in the use of selective COX-2 inhibitors was hampered by concerns about long-term cardiovascular toxicity with these drugs.

Key Points: Drugs for Overactive Bladder

- Theoretically, calcium antagonists and potassium channel openers would be attractive methods to inhibit DO and regulate detrusor smooth muscle tone. However, there is no current clinical evidence to support the use of either class of drug in the treatment of bladder dysfunction. The use of α-AR antagonists to treat storage symptoms in men, as distinct from their effect on voiding symptoms, is somewhat unclear. Some studies suggest no effect of commonly used agents, whereas other studies suggest that selective blockade of α_{1A}-ARs is clinically effective, albeit associated with a high incidence of ejaculatory dysfunction. In women, treatment of OAB filling and storage symptoms with α_{1A}-AR antagonists seems ineffective.
- The most recent drug approved for the treatment of OAB is a β_3-AR agonist, mirabegron, which acts both to relax and maintain low detrusor tone during filling and also to inhibit activity in sensory afferents in an animal model. In such a model, these drugs increase bladder capacity but do not change voiding pressure or voiding volume. Clinically, mirabegron, the only such agent currently available, improves OAB symptoms without affecting emptying parameters. The side-effect profile is quite different from that of the antimuscarinic agents, and some concern exists regarding negative cardiovascular effects (blood pressure and HR); in clinical studies, these have been minimal and clinically not relevant, but it has been recommended that these be monitored during treatment.
- There are logical theoretic mechanisms whereby PDE inhibitors should enhance the relaxation of LUT smooth muscle. PDE5 inhibitors have been shown to have beneficial effects on LUTS, including those of OAB, although their site(s) and mechanism(s) remains to be established.
- Although there are theoretic mechanisms by which tricyclic antidepressants, particularly imipramine, should facilitate storage both by decreasing bladder contractility and increasing outlet resistance, there are no good-quality RCTs to adequately test this hypothesis. Duloxetine, primarily a noradrenalin-serotonin reuptake inhibitor, has been shown to increase some significant storage symptoms, but trials directed specifically toward this effect are lacking. Although there are theoretic mechanisms by which prostaglandin synthesis inhibitors could affect filling and storage

symptoms, clinical evidence for this is scarce.

Other Drugs

Dimethyl Sulfoxide.

Dimethyl sulfoxide (DMSO) is a relatively simple, naturally occurring organic compound that has been used as an industrial solvent for many years. It has multiple pharmacologic actions (membrane penetrant, anti-inflammatory, local analgesic, bacteriostatic, diuretic, cholinesterase inhibitor, collagen solvent, vasodilator) and has been used for the treatment of arthritis and other musculoskeletal disorders, usually in a 70% solution. The formulation for human intravesical use is a 50% solution. Sant (1987) has summarized the pharmacology and clinical use of DMSO and has tabulated “good to excellent” results in 50% to 90% of collected series of patients treated with intravesical instillation for interstitial cystitis (Sant, 1987). **However, DMSO has not been shown to be useful in the treatment of NDO or IDO or in any patients with urgency or frequency but without interstitial cystitis.** The subject of interstitial cystitis and its treatment is considered in Chapter 14.

Baclofen.

γ-Aminobutyric acid (GABA) is a ubiquitous inhibitory neurotransmitter in the CNS that can inhibit the micturition reflex at several points along its central pathway (de Groat, 1997; Pehrson and Andersson, 2002). Experimental data suggest the GABAergic system as an interesting target for bladder dysfunction therapy. Baclofen intrathecally attenuated oxyhemoglobin-induced DO, suggesting that the **inhibitory actions of GABA-B–receptor agonists in the spinal cord may be useful for controlling micturition disorders caused by C-fiber activation in the urothelium and/or suburothelium** (Pehrson and Andersson, 2002). In spinal-intact rats, intrathecal application of bicuculline induced detrusor-sphincter dyssynergia (DSD)–like changes, whereas intrathecal application of baclofen induced urethral relaxation during isovolumetric bladder contractions (Miyazato et al., 2008). Miyazato et al. (2008) found signs of hypofunction of the GABAergic system after SCI (glutamate decarboxylase 67 mRNA levels in the spinal cord and dorsal root ganglia were decreased) and showed that activation of GABA-A and GABA-B receptors in the spinal cord inhibited DO, as evidenced by a reduction in nonvoiding contractions. GABA-B–receptor activation preferentially reduced DO before inhibiting voiding contractions, whereas GABA-A–receptor activation inhibited DO and voiding contractions at the same concentration.

As a GABA agonist on GABA-B receptors, baclofen was used orally in IDO patients. However, its efficacy was poor, eventually dictated by the fact that baclofen does not cross the blood-brain barrier (Taylor and Bates, 1979). Baclofen is one of the most effective drugs for the treatment of spasticity after SCI, traumatic or hypoxic brain injury, and cerebral palsy (Ochs, 1993), and *intrathecal* baclofen was shown to be useful in some patients with spasticity and bladder dysfunction (Bushman et al., 1993). Baldo et al. (2000) found a rapid (24 hours) and persistent increment in the volume to first detrusor contraction and of the maximal cystometric capacity, whereas maximal detrusor pressure decreased. At 10 days, the volume to first detrusor contraction had increased from 143 mL to 486 mL. In selected patients with spasticity and bladder dysfunction, intrathecal baclofen seems to be an effective therapy.

Combinations

α_{1A}-AR Antagonists With Antimuscarinics.

Traditionally, male LUTS were thought to result from BPO secondary to BPE. However, **male LUTS may arise from prostatic pathology, bladder dysfunction, or both.** Thus, diagnosis and appropriate treatment of men with OAB symptoms are complex and difficult. α_1-AR antagonists remain the most widely used pharmacologic agents for relief of bladder outflow resistance, as they relax prostatic and urethral smooth muscle tone, the dynamic component of BPO (Andersson and Gratzke, 2007; Lepor et al., 2012). In contrast, antimuscarinics, which function by competitively blocking the muscarinic receptors, are the first-line pharmacologic treatment for OAB (Andersson et al., 2009). Given the prevalence of combined voiding and OAB symptoms and the finding that the QoL of these patients is affected primarily by the symptoms of OAB, it might be logical for this category of patients to be given antimuscarinic drugs (Ruggieri et al., 2005).

A variety of such combinations have been evaluated. **Several randomized, controlled trials demonstrated that the combination treatment of antimuscarinic drugs and α_1-AR antagonists was more effective at reducing male LUTS than α_1-AR antagonists alone in men with OAB and coexisting BPO** (Athanasopoulos et al., 2003; Lee et al., 2004, 2005; Kaplan et al., 2006, 2007, 2013; Saito et al., 1999; van Kerrebroeck et al., 2013a, 2013b). Saito et al. (1999) reported therapeutic benefit of combining an antimuscarinic agent (propiverine) with an α_1-AR antagonist (tamsulosin), as compared with an α_1-AR antagonist alone. The rates of improvement in daytime frequency, incontinence, and urgency were greater in the combination group than the α_1-AR antagonist–alone group. **The PVR was unchanged** in both groups, and there was only one case (1.5%) of AUR with the combined treatment.

Subsequently, Lee et al. (2005) compared the efficacy and safety of combination therapy with propiverine and doxazosin in 211 men with urodynamically confirmed BOO and OAB symptoms for 8 weeks. Compared with the doxazosin arm, the patients in the combination therapy group showed greater improvement in urinary frequency, average micturition volume, and storage and urgency scores of IPSS. Patient satisfaction was significantly higher in the combination group. There was also a significant increase in PVR (+20.7 mL) in the combination group, but no case of urinary retention was reported.

A large-scale, multicenter, randomized, double-blind, placebo-controlled trial **(the TIMES study)** demonstrated the efficacy and safety of tolterodine ER alone, tamsulosin alone, and the combination of both in 879 men with OAB and BPO (Kaplan et al., 2006). In the primary efficacy analysis, 172 men (80%) receiving tolterodine ER plus tamsulosin reported treatment benefits by week 12 ($P < .001$ vs. placebo; $P = .001$ vs. tolterodine ER; $P = .03$ vs. tamsulosin). In the secondary efficacy analysis, patients receiving tolterodine ER plus tamsulosin compared with placebo experienced small but significant reductions in urgency incontinence, urgency episodes, daytime frequency, and nocturia. However, there were no significant differences between tamsulosin monotherapy and placebo for any diary variables at week 12. Patients receiving tolterodine ER plus tamsulosin demonstrated significant improvements in total IPSS (−8.02 vs. placebo −6.19, $P = .003$) and QoL (−1.61 vs. −1.17, $P = .003$). Although there were significant improvements in the total IPSS among patients who received tamsulosin alone, the differences in total IPSS among patients who received tolterodine ER versus placebo were not significant. **The combination of antimuscarinics and α_1-AR antagonists may be the most effective therapy in men with OAB symptoms in the presence of BPO.**

A subanalysis of data from the TIMES study focused on the urgency perception scale and concluded that the group of 217 men who received tolterodine plus tamsulosin showed significantly improved urgency variables and patient-reported outcomes (Rovner et al., 2008a). Moreover, this group of patients reported increased satisfaction with the treatment and willingness to continue the treatment. Another subanalysis of data from the TIMES study examined the effects of the drugs on urinary symptoms as assessed by the IPSS (Kaplan et al., 2008a). Based on this subanalysis, the authors concluded that tolterodine ER plus tamsulosin was significantly more effective than placebo in treating storage LUTS, including OAB symptoms. However, these results should be considered with caution because they were derived from post hoc analysis of the TIMES data.

Maruyama et al. (2006) **reported different results** in their prospective, randomized controlled study in which naftopidil (25 to 75 mg/day), an α_{1D}-AR antagonist, alone or in combination with propiverine hydrochloride (10 to 20 mg/day) or oxybutynin hydrochloride (2 to 6 mg/day), was administered for 12 weeks to 101 BPH patients. In the study, the IPSS and QoL index score improved significantly in both groups, with no marked differences between groups. Qmax and PVR tended to improve in both groups, again with no differences between groups. However, median post-therapeutic PVR was significantly larger in the combination group (45.0 mL) than in the monotherapy group (13.5 mL, $P = .021$). There were significantly more patients with increased residual urine volume relative to unchanged residuals in the combination therapy group (22.9%) versus the monotherapy group (5.0%, $P = .038$). **The authors of this study concluded that combination therapy with a low-dose antimuscarinic agent was not more effective than monotherapy.** Moreover, although they did not encounter any cases of urinary retention, the percentage of patients with increased residual urine volume was significantly greater in the combination therapy group than in the monotherapy group.

Kang et al. (2009) published the results of another study using low-dose antimuscarinic therapy. They evaluated the efficacy and safety of combined treatment with tamsulosin 0.2 mg and propiverine hydrochloride 10 mg compared with tamsulosin monotherapy. After 3 months, both groups showed significant improvements in IPSS, QoL, voided volume, Qmax, and PVR, but only the QoL index was significantly different between groups in favor of the combination group. No cases of AUR were recorded in this low-dose study.

The efficacy and safety of solifenacin in combination with tamsulosin were assessed in several large-scale RCTs, including the VICTOR trial (Kaplan et al., 2013) and the SATURN trial (Van Kerrebroeck et al., 2013a). The VICTOR trial was a randomized, placebo-controlled study assessing solifenacin 5 mg as an add-on therapy to α_1-AR antagonists treatment in men with residual OAB symptoms (Kaplan et al., 2013). Significant reductions in daytime frequency, the primary outcome of the study, were achieved in both solifenacin (and tamsulosin) and placebo (and tamsulosin) trials compared with baseline, but the difference between the two drug groups was not significant. Solifenacin add-on significantly reduced daily urgency episodes compared with placebo, but this was the only significant efficacy difference between solifenacin and placebo. Seven patients (3%) in the solifenacin group developed retention problems, with three requiring catheterization, versus none in the placebo group. The SATURN study was a randomized, placebo-controlled trial evaluating the combination of different doses of solifenacin (3, 6, and 9 mg/day) with tamsulosin versus tamsulosin alone in men with voiding and storage LUTS (Van Kerrebroeck et al., 2013a). Decreases in micturition frequency and total urgency and frequency scores and increases in void volume per micturition were significantly greater with increasing solifenacin dosage in the combination groups versus with tamsulosin monotherapy. In a post-hoc analysis, patients with at least two urgency episodes and at least eight micturitions per 24 hours at baseline showed clear improvements in storage and QoL parameters with combination treatment over tamsulosin alone. The subgroup of patients with fewer storage symptoms experienced little or no additional benefit from combination therapy compared with tamsulosin monotherapy. Combination therapy was well tolerated, and adverse events were consistent with the safety profiles of each individual compound. Mean PVR volume increased with increasing solifenacin dose, but the changes were not clinically relevant and were not accompanied by an increase in the incidence of retention.

A meta-analysis compared the efficacy and safety of treatment with α-blockers and anticholinergics to α-blocker monotherapy among men with storage urinary symptoms related to benign prostatic hyperplasia (BPH) (Filson et al., 2013). Combination therapy produced a significantly greater reduction in IPSS storage subscore (Δ –0.73, 95% CI –1.09 to –0.37) and voiding frequency (Δ –0.69 voids, 95% CI –0.97 to –0.41) than monotherapy. There was also a greater reduction in Qmax (Δ –0.59 mL/sec, 95% CI –1.04 to –0.14) and an increase in PVR (Δ 11.60 mL, 95% CI 8.50 to 14.70) with combination therapy. The number of patients needed to be treated with combination therapy to cause one acute urinary retention episode was 101.

The efficacy and safety of a fixed-dose combination (FDC) tablet containing solifenacin 6 mg plus an oral controlled absorption system (OCAS) formulation of tamsulosin (TOCAS) 0.4 mg has been studied in a phase III trial

(NEPTUNE). NEPTUNE, which included 1334 men with LUTS/BPH who had moderate-to-severe storage symptoms and voiding symptoms, showed that an FDC of solifenacin 6 mg plus TOCAS improved storage symptoms and QoL compared with TOCAS alone (van Kerrebroeck et al., 2013b). FDC treatment was also well tolerated and exhibited an adverse-event profile similar to those reported for the individual monotherapies. Consequently, a once-daily FDC tablet of solifenacin 6 mg plus TOCAS 0.4 mg aimed at treating both storage and voiding symptoms in men with LUTS/BPH is licensed and available in several countries, including the United Kingdom. NEPTUNE and NEPTUNE II open-label extension studies further evaluated the long-term (up to 52 weeks) safety and efficacy of flexible dosing of two FDCs of solifenacin plus TOCAS (solifenacin 6 mg plus TOCAS 0.4 mg or solifenacin 9 mg plus TOCAS 0.4 mg) in men with moderate-to-severe storage and voiding symptoms (Drake et al., 2015). Reductions in total IPSS and total urgency and frequency score (TUFS) during NEPTUNE were maintained for up to 52 weeks of FDC treatment, with mean reductions of 9.0 (standard deviation [SD]: 5.7) and 10.1 (SD: 9.2), respectively, from baseline to end of treatment. Urinary retention occurred in 13 of 1208 (1.1%) patients receiving one or more FDCs in NEPTUNE and/or NEPTUNE II; 8 (0.7%) required catheterization. Responder and health-related QoL (HRQoL) analyses of the NEPTUNE study reported that men treated with an FDC of solifenacin 6 mg plus TOCAS consistently had significantly improved outcomes compared with both the placebo and TOCAS (Drake et al., 2016). There was a significant correlation between the reduction in total urgency frequency score and the improvement in HRQoL defined by the IPSS-QoL score, the OAB-q symptom bother score, the overall patient global impression bladder symptoms, and the general health of the patient. Drake et al. expected that the positive HRQoL data for FDC of solifenacin 6 mg plus TOCAS are likely to translate into improved persistence of treatment and possibly increased confidence to prescribe combined therapy as the initial treatment for moderate-to-severe LUTS/BPH (Drake et al., 2016).

Medical therapy to reduce DO in a neurogenic bladder has focused on antimuscarinic therapy, which increases bladder capacity, decreases bladder filling pressure, and improves compliance (Goessl et al., 1998; Stöhrer et al., 2009). Although use of antimuscarinics combined with clean intermittent catheterization (CIC) is the most commonly recommended medical therapy for neurogenic bladder, the results are sometimes unsatisfactory, and many patients continue to have poor bladder compliance and remain incontinent (Razdan et al., 2003). McGuire and Savastano (1985) reported that α-AR antagonists decreased bladder pressure with filling and increased capacity, and that the addition of an antimuscarinic enhanced these effects, indicating that α-AR antagonists and the antimuscarinic had a synergistic effect on detrusor tone in the decentralized bladder. This finding led to the widespread use of α_1-AR antagonists in the treatment of neurogenic bladder (Abrams et al., 2003; Chancellor et al., 1994; Swierzewski et al., 1994). Swierzewski et al. (1994) treated 12 patients with SCI who had poor bladder compliance, despite therapy with CIC and an antimuscarinic, with 5 mg of terazosin for bladder management. After 4 weeks, compliance increased by 73%, bladder pressure decreased by 36 cm H_2O, and capacity increased by 157 mL. **These results support the assumption that α_1-AR antagonists and antimuscarinics may have an additional synergistic effect on the bladder in the neurogenic population.**

In a retrospective chart review, combination therapy with an antimuscarinic agent, an α_1-AR antagonist, and imipramine produced superior results to those obtained using a single agent in patients with neurogenic bladder dysfunction (Cameron et al., 2009). These patients showed significant improvement in clinical parameters and compliance and decreased bladder pressures at capacity. It has been shown that in the decentralized human detrusor, there may be an increase in α-AR sites and a switch to α-AR–mediated contractile function from the typical β-AR–mediated relaxation function during bladder filling (Sundin et al., 1977). Imipramine is a systemic muscarinic-receptor antagonist and a direct smooth muscle inhibitor that also blocks the reuptake of serotonin and noradrenaline. This suggests that targeting multiple receptors may maximize the effectiveness of pharmacologic treatment of neurogenic bladder and should be considered in patients in whom treatment with antimuscarinics alone fails.

β_3-AR Agonist With Antimuscarinics.

β_3-AR agonists are believed to exert their therapeutic effects through stimulation of adenylyl cyclase and activation of potassium K^+ channels, but also through other mechanisms. The former leads to an increase in cAMP and the latter to hyperpolarization, both of which result in relaxation. The beneficial effects of modulation of these pathways are inhibition of spontaneous activity, increased bladder compliance (decreased bladder tone during filling), greater distention needed to activate the micturition reflex (increased bladder capacity), and decreased afferent activity, with no effect on voiding contraction (no risk for urinary retention).

These mechanisms are distinct from those of antimuscarinic therapies used to treat OAB. Accordingly, the combination of these two types of medications is being investigated to determine whether concomitant use can result in increased efficacy with an acceptable profile of safety and tolerability. Based on results with an animal model, it was concluded that the “combination of antimuscarinics and β_3-AR agonists can result in increased efficacy and potency and supports the hypothesis that combining these compound classes in the clinic could have beneficial effects in treating urinary bladder dysfunction” (Rekik et al., 2013).

Abrams et al. reported results of a phase II trial (Symphony) of combination treatment with mirabegron and solifenacin in patients with OAB (Abrams et al., 2015). A total of 1306 patients were randomly assigned to 12 groups: placebo, 6 combination groups (solifenacin 2.5, 5, or 10 mg plus mirabegron 25 or 50 mg), and 5 monotherapy groups (solifenacin 2.5, 5, or 10 mg, or mirabegron 25 or 50 mg) for a 12-week treatment period. The primary end point was change from baseline to end of treatment in mean volume voided per micturition (MVV). All combinations with solifenacin 5 or 10 mg improved MVV significantly comparing to solifenacin 5 mg monotherapy, and a decreasing trend in the mean number of micturitions per 24 hours was observed with increasing solifenacin and mirabegron doses. The three drug combinations (solifenacin 5 mg plus mirabegron 50 mg, solifenacin 10 mg plus mirabegron 25 mg, and solifenacin 10 mg plus mirabegron 50 mg) demonstrated significant improvements compared with both solifenacin 5 mg and placebo. No severe adverse events were reported, and treatment was generally well tolerated. In Japan, Yamaguchi et al. conducted a multicenter, open-label, phase IV study (MILAI study) to assess the safety and efficacy of mirabegron in combination with solifenacin in OAB patients who were being treated with solifenacin 2.5 mg or 5 mg once daily for at least 4 weeks (Yamaguchi et al., 2015). A total of 223 patients were randomly assigned to one of four groups: solifenacin 2.5 mg plus mirabegron 25 mg ($n = 35$), solifenacin 2.5 mg plus mirabegron 50 mg ($n = 37$), solifenacin 5 mg plus mirabegron 25 mg ($n = 58$), or solifenacin 5 mg plus mirabegron 50 mg ($n = 93$) for a 16-week treatment period. The overall incidence of drug-related TEAEs was 23.3%, and all TEAEs were mild or moderate. All treatments showed significant improvements in OABSS total score, overactive bladder questionnaire short form (OAB-q SF) score (symptom bother and total HRQoL score), mean number of micturitions in 24 hours, mean number of urgency episodes in 24 hours, mean number of UI episodes in 24 hours, mean number of urgency UI episodes in 24 hours, mean volume voided per micturition, and mean number of nocturia episodes per night. Recently, a phase IIIB trial (BESIDE) in incontinent OAB patients was carried out in Europe (Drake et al., 2016). Patients with OAB ($n = 2174$), who remained incontinent despite solifenacin 5 mg once daily during a 4-week single-blind run-in, were randomized 1 : 1 : 1 to a double-blind daily combination ($n = 727$), solifenacin 5 mg ($n = 728$), or 10 mg ($n = 719$) for 12 weeks. The primary efficacy end point was change in mean number of incontinence episodes per 24 hours. Key secondary efficacy end points were change in mean number of micturitions per 24 hours and the number of incontinence episodes noted in the 3-day voiding diary. All combinations significantly improved daily incontinence episodes ($P = 0.001$), daily micturitions ($P < 0.001$), and incontinence noted in a 3-day voiding diary ($P = 0.014$) compared with solifenacin 5 mg monotherapy. The combination of drugs was not inferior to solifenacin 10 mg for key secondary end points and was superior to solifenacin 10 mg for improving daily micturitions. All treatments were well tolerated. These results suggest that combination therapy of mirabegron 50 mg with solifenacin 5 mg may be an alternative to dose escalation of solifenacin in patients with insufficient response to solifenacin 5 mg monotherapy.

β_3-AR Agonist With α_{1A}-AR Antagonists.

Ichihara et al. (2015) evaluated the efficacy and safety of add-on treatment with mirabegron for overactive bladder symptoms remaining after α_1-AR antagonist (tamsulosin) treatment in men with benign prostatic obstruction. The change in PVR urine volume was significantly greater in the combination group. Six patients (out of 76) experienced adverse events in the combination group, and urinary retention was observed in 1 patient. Nevertheless, the authors concluded that the combination was effective and safe in these patients.

Combined Antimuscarinics.

Although antimuscarinic agents are the first choice of treatment for patients with OAB symptoms, these drugs do not always lead to the desired effect of detrusor stability and continence, especially for patients with SCI or neurologic diseases such as multiple sclerosis or meningomyelocele. In these patients, the goal of urologic therapy is to maintain continence and to reduce intravesical pressure. When antimuscarinic treatment fails, however, invasive procedures such as the injection of botulinum neurotoxin type A (BoNTA), intravesical application of drugs, or surgery are necessary.

Amend et al. (2008) evaluated a combined antimuscarinic regimen as a noninvasive alternative for patients who had neurogenic bladder dysfunction with incontinence, reduced bladder capacity, and increased intravesical pressure. They added secondary antimuscarinics to the existing double-dose antimuscarinics for patients who previously demonstrated unsatisfactory outcomes with double-dose antimuscarinic monotherapy. The study drugs were tolterodine, oxybutynin, and trospium. After a 4-week combined regimen, incontinence episodes decreased, and reflex volume, maximal bladder capacity, and detrusor compliance increased. Side effects were comparable to those seen with normal-dose antimuscarinics. Those positive findings were speculated to be the result of (1) additive or synergistic activation of different muscarinic receptors or interactions of receptors on different parts of the bladder wall, (2) undiscovered faster metabolism of antimuscarinics requiring an increased dose of different antimuscarinic drugs, and/or (3) downregulation of subdivisions of antimuscarinic receptors under monotherapy that may lead to better susceptibility of other subdivisions when treated by the second drug.

Kosilov et al. evaluated the effectiveness of cyclic therapy of combined high-dose trospium and solifenacin depending on severity of OAB symptoms in elderly men and women (Kosilov et al., 2014a,b, 2016). They found that cyclic therapy of high-dose solifenacin and trospium in elderly patients with moderate-to-severe symptoms of OAB enabled patients to maintain a longer therapeutic effect with an acceptable level of side effects (Kosilov et al., 2014a). They conducted another study to evaluate the efficiency of treatment for severe symptoms of OAB with cyclic therapy of combined antimuscarinic drugs in elderly men and women and determined that cyclic therapy with combined antimuscarinics appeared to be effective for controlling severe OAB in elderly patients, increasing the compliance level (76% to 84%). However, continuous therapy with standard doses of trospium and solifenacin results in low adherence and high rates of treatment withdrawal (≥66%) despite satisfactory clinical and urodynamic results.

The effectiveness of combination therapy with two different antimuscarinics was also evaluated in patients with severe symptoms of OAB and BPH (Kosilov et al., 2015b, 2016). Patients in the experimental group for 2 months received treatment with a daily combination of solifenacin 5 mg and trospium 5 mg simultaneous with tamsulosin 0.4 mg. Patients in the control group were treated only with tamsulosin. In the experimental group, the number of episodes of incontinence reduced from a moderate level of 3.4 (0.8) per day to 0.9 (0.7) per day, and most urodynamic indices normalized significantly. In the control group, changes in urodynamic indices were not significant. The quantity of side effects did not exceed the level that is commonly found in patients receiving antimuscarinic monotherapy. The authors concluded that a combination of trospium and solifenacin in standard doses is an efficient and safe method for managing severe symptoms of OAB over the course of treatment with tamsulosin in patients with OAB/BPH (Kosilov et al., 2016). However, in patients with OAB/BPH, the efficacy and side effects of combination therapy using different antimuscarinics should be further evaluated.

The combined regimen needs further investigation to verify its efficacy as a noninvasive alternative for patients in whom antimuscarinic monotherapy fails.

Antimuscarinics and 5α-Reductase Inhibitors.

The standard first-line medical therapy for men with moderate-to-severe LUTS is an α_1-AR antagonist, a 5α-reductase inhibitor, or combination therapy with both. Both α_1-AR antagonists and 5α-reductase inhibitors alleviate LUTS in men by reducing bladder outlet resistance. **α_1-AR antagonists decrease smooth muscle tone in the prostate and bladder neck, whereas 5α-reductase inhibitors reduce prostate volume. As mentioned, several trials have demonstrated the efficacy and safety of combination therapy with antimuscarinics and α_1-AR antagonists for patients with OAB and coexisting BPO. However, post hoc analyses of the TIMES study** (Kaplan et al., 2006) **suggested that men with smaller prostates benefit more from antimuscarinic therapy than those with larger prostates** (Roehrborn et al., 2008a, 2009). Chung et al. (2010) conducted an open-label, fixed-dose study to assess the efficacy and safety of tolterodine ER in combination with dutasteride in men with a large prostate (≥30 g) and persistent OAB symptoms after α_1-AR antagonist therapy who had been unsuccessfully treated with dutasteride alone. At the start of the study, all patients had been on dutasteride 0.5 mg daily for at least 6 months, and α_1-AR antagonist therapy had failed. All patients were given 4 mg of tolterodine ER daily for 12 weeks and had discontinued α_1-AR antagonist therapy before the start of the study. At 12 weeks, the frequency (−3.2/24 hour, $P < .02$), urgency (19.2%, $P < .03$), number of severe OAB episodes (71.4%, $P < .05$), and incidence of nighttime voiding (−0.9, $P < .003$) were found to have decreased significantly from baseline. The IPSS decreased with dutasteride treatment (from 19.3 to 14.3) and further decreased with the addition of tolterodine to 7.1 ($P < .001$). Storage symptoms decreased from 9.8 to 4.5 ($P < .001$). Dry mouth occurred in four (7.5%) patients, constipation in one (2%), and decreased sexual function in two (3.9%). PVR increased by 4.2 mL, Qmax decreased by 0.2 mL/sec, and no patients developed retention. The authors concluded that the combination of tolterodine and dutasteride was effective, safe, and well tolerated in men with large prostates with persistent OAB symptoms and LUTS secondary to BPO.

Dutasteride was evaluated in terms of OAB symptoms and bladder ischemia in men with BPE (Wada et al., 2015). Twenty-four weeks after dutasteride treatment, bladder vascular resistive index (RI) significantly decreased, and urgency score of IPSS was significantly improved from 2.3 ± 1.9 to 1.4 ± 1.4 ($P < 0.01$). In 20 patients with persistent urgency after dutasteride, RI was less improved than in an additional 10 patients without urgency. Posttreatment bladder outlet obstruction index (BOOI) and PdetQmax in patients with persistent urgency were significantly higher than in those without urgency after dutasteride. The authors suggested that reduction of obstruction and improvement of bladder ischemia might play important roles in the beneficial impact of dutasteride on OAB symptoms.

The results of this study indicate that antimuscarinics are safe and effective in selected patients with OAB and BPO when used in combination with 5α-reductase inhibitors. Further studies are required to verify the efficacy of antimuscarinics combined with 5α-reductase inhibitors in these patients.

α_1-AR Antagonists With 5α-Reductase Inhibitors.

It has been **well established that the combinations of α_1-AR antagonists with 5α reductase inhibitors** (doxazosin finasteride in the Medical Therapy of Prostatic Symptoms **[MTOPS]** trial; dutasteride plus tamsulosin in the Combination of Avodart and Tamsulosin **[CombAT]** study) **can improve clinical outcomes and reduce the incidence of BPH and LUTS progression** measured as symptom worsening, retention, or progression to surgery (McConnell et al., 2003; Roehrborn et al., 2010). A combination of α_1-AR antagonist with a 5α-reductase inhibitor is recommended by the American

Urological Association (AUA) and European Association of Urology (EAU) for men with bothersome moderate-to-severe LUTS, high risk for disease progression-enlarged prostate (prostate volume >40 mL), and higher prostate specific antigen (PSA) (McVary et al., 2011; Oelke et al., 2013). The possible disadvantage of combinations of α_1-AR antagonists with 5α-reductase inhibitors is the increased incidence of adverse events, because there are concomitant effects of both classes of drugs (Fullhase et al., 2013; La Torre et al., 2016). Potential side effects (e.g., ejaculation dysfunction with α_1-AR antagonists or loss of libido with 5α-reductase inhibitors) might be additive and may negatively affect patient QoL and, especially, sexual function.

Key Points: Drugs for Male Lower Urinary Tract Symptoms

- Because male LUTS may arise from prostatic obstruction, bladder dysfunction, or both, a logical step is to combine an α_1-AR antagonist with antimuscarinics to treat such patients. There are several trials demonstrating that this combination is more effective at reducing male LUTS than just α_1-AR antagonists alone in men with OAB and BPO. In these trials, the PVR was unchanged. However, there is no universal agreement because other trials do not show effects. Such usage has been recorded in patients with NDO with successful results.
- Because β_3-AR agonists and antimuscarinics have different mechanisms of action, it is attractive to speculate that a combination would be more effective than either drug used alone, especially because the adverse-effect profiles are different. Such trials are ongoing.
- Also under investigation is the combination of different antimuscarinic agents in patients in whom antimuscarinic monotherapy fails.
- Antimuscarinic therapy in patients with OAB symptoms and prostatic pathology is more effective in men with smaller prostates.
- It is well established that the combination of an α-AR antagonist and a 5α-reductase inhibitor will improve clinical outcomes and reduce the incidence of symptomatic progression in patients with LUTS and BPH or BPO.

Toxins

Intravesical pharmacologic therapy for LUTS stems from the fact that circumventing systemic administration of active compounds offers two potential advantages. First, high concentrations of pharmacologic agents can be given to the bladder tissue, producing enhanced local effects. Second, drugs inappropriate for systemic administration because of off-target effects can be safely used. Attractive as it may be, intravesical pharmacologic therapy should still be considered as a second-line treatment in patients who are refractory to oral therapy or who do not tolerate its systemic side effects. However, this statement is based on the assumption that intervention therapy should follow oral medication. Research aiming at defining if patient subgroups will benefit from intravesical therapy as first-line treatment is clearly necessary.

Botulinum Toxin

Mechanism of Action.

Botulinum toxin (BoNT) is a **neurotoxin** produced by *Clostridium botulinum*. **Of the seven subtypes of BoNT, subtype A (BoNTA) has the longest duration of action, making it the most relevant clinically.** BoNTA is available in four different commercial forms, with the proprietary names of Botox, Dysport, Xeomin, and Prosigne. Although the toxin is the same, it is wrapped by different proteins that modify the relative potency of each brand. This was the basis for the introduction of the nonproprietary names onabotulinumtoxinA (onabotA), abobotulinumtoxinA (abobotA), and incobotulinumtoxinA (incobotA) for Botox, Dysport, and Xeomin, respectively. Prosigne is the proprietary name of a BoNTA produced in China, which currently does not have a known nonproprietary name. Although the potency of each one is usually expressed in units (U), the doses are not interchangeable. **Clinical dose conversion studies for the LUT do not exist.** Available information indicates that onabotA is roughly three times more potent than abobotA and equivalent to incobotA. Nevertheless, these equivalences should be approached with caution.

Most of the information available about intravesical application of BoNTA derives from the use of onabotA (Botox). However, in addition to subtype A, some studies have investigated the effect of detrusor injection subtype B, rimabotulinumtoxinB (proprietary names being Miobloc or Neurobloc according to countries).

BoNT consists of a heavy and a light chain linked by a disulfide bond. In the synaptic cleft, the toxin binds to synaptic vesicle protein 2 (SV2) by the heavy chain before being internalized by the nerve terminal along with the recycling process of synaptic vesicles (Dong et al., 2006). The two chains are then cleaved, and the light chain passes into the cytosol, where it cleaves the attachment proteins involved with the mechanism of fusion of synaptic vesicles to the cytoplasmic membrane necessary for neurotransmitter release. Attachment proteins (SNARE [soluble *N*-ethylmaleimide sensitive factor attachment protein receptor]) include synaptosome-associated protein 25 kD (SNAP-25), synaptobrevin (vesicle-associated membrane protein [VAMP]), and syntaxin. **BoNTA cleaves SNAP-25, rendering the SNARE complex inactive** (Chancellor et al., 2008a; Humeau et al., 2000). Subtype B acts preferentially through the inactivation of VAMP (Humeau et al., 2000).

BoNTA application was extensively evaluated in striated muscle. In this tissue, paralysis occurs by prevention of ACh release from cholinergic motor nerve endings (Humeau et al., 2000). Accumulation of neurotransmitter-containing synaptic vesicles is followed by terminal axonal degeneration. Striated muscle paralysis recovers within 2 to 4 months. During this time, axons develop lateral sprouts and eventually regenerate completely (de Paiva et al., 1999).

In the human bladder, SV2 and SNAP-25 expression has been demonstrated in parasympathetic, sympathetic, and sensory fibers (Coelho et al., 2010, 2012a, 2012b). Almost all parasympathetic nerves express the two proteins (Coelho et al., 2010, 2012a). Because these nerves play a fundamental role in detrusor contraction during voiding, **the blockade of ACh release is believed to play an essential role in detrusor hypocontractility or acontractility that follows BoNTA injection in the bladder.** In accordance with this view, it was shown that in normal or spinal cord–injured animals, BoNTA treatment decreased the bladder contractions evoked by electrical stimulation of spinal nerves without altering intrinsic contractions (Ikeda et al., 2012). However, cholinergic axon sprouting concomitant with clinical remission could not be documented in the detrusor (Haferkamp et al., 2004).

Bladder sensory impairment is also expected to play an important role in the final effect of BoNTA bladder injection. BoNTA inhibits the spinal cord release of glutamate, substance P (SP), and calcitonin gene–related peptide (CGRP) from sensory nerves (Aoki, 2005; Meng et al., 2007; Purkiss et al., 2000) **and the release of neuropeptides at the peripheral extremities** (Lucioni et al., 2008; Rapp et al., 2006)**. BoNTA has also been shown to reduce the**

suburothelium immunoreactivity for transient receptor potential (TRP) channel TRPV1 or $P2X_3$ (Apostolidis et al., 2005b)**. Morenilla-Palao et al.** (2004) **have shown that BoNTA impedes TRPV1 trafficking from intracellular vesicles to the neuronal membrane, a process that is also dependent on SNARE proteins. All of these mechanisms may contribute to the recent observation that BoNTA reduces afferent firing from bladder afferents and antidromic release of neuropeptides** (Ikeda et al., 2012). Although SV2 and SNAP-25 immunoreactivity has not been detected in urothelial cells (Coelho et al., 2010), urothelial function also seems compromised after BoNTA administration. BoNTA has been shown to inhibit ATP release from urothelium in animal models of SCI (Khera et al., 2004; Smith et al., 2008). Therefore, it is not surprising that administration of BoNTA to inflamed rat bladders reduces spinal c-Fos counts at the L6 and S1 spinal cord segments (Vemulakonda et al., 2005).

Cleaved, inactive SNAP-25 appears rapidly after BoNTA injection. In the guinea pig, a robust expression of cleaved SNAP-25 could be detected already at 12 hours, and maximum intensity could be detected at 24 hours with little changes afterward. In guinea pigs, cleaved SNAP-25 expression was restricted to nerve fibers. Almost all parasympathetic fibers, either preganglionic or postganglionic, were affected, whereas less than one-half of the sensory fibers expressed the cleaved protein (Coelho et al., 2012a, 2012b). In the human urinary bladder, cleaved SNAP-25 could be detected in NDO patients up to 11 months after BoNTA injection (Schulte-Baukloh et al., 2007). The longer duration of cleaved SNAP-25 in the detrusor smooth muscle, longer than in striated muscles, has no firm explanation at the present time. However, the longer persistence of the inactive form of SNAP-25 plus the involvement of preganglionic and postganglionic parasympathetic neurons may contribute to persistence of the BoNTA effect in the bladder.

Myofibroblasts form a syncytium through extensive coupling via the gap-junction protein connexin 43 and have close contacts with sensory nerves. These facts led to the hypothesis that myofibroblasts act as modulators of bladder behavior (Apostolidis et al., 2006; Wiseman et al., 2003). However, the expression of connexin 43 is not altered by BoNTA (Roosen et al., 2009). Hence, at the present time, firm evidence for the action of BoNTA on myofibroblasts is scant.

BoNTA may decrease the levels of neurotrophic agents in the bladder tissue. Levels of nerve growth factor (NGF) (Giannantoni et al., 2006, 2013; Liu et al.,

2009) and brain-derived neurotrophic factor (BDNF) (Pinto et al., 2010) have been shown to decrease in the bladder and/or urine after BoNTA injection. Because both neurotrophins have paramount roles in growth, maintenance, and plasticity of peptidergic sensory nerves, these findings may point toward another mechanism whereby BoNTA acts on the bladder.

Clinical Use.

Comprehensive reviews of the clinical use of BoNTA have been produced during the past few years, covering different aspects of this treatment (Andersson et al., 2013a, 2017; Apostolidis et al., 2009; Chapple and Patel, 2006; Cruz et al., 2011; Denys et al., 2012; Dowson et al., 2011, 2012; Duthie et al., 2011; Fowler et al., 2012; Herschorn et al., 2011a; Karsenty et al., 2008; Kuo, 2005a, 2005b, 2007; Mangera et al., 2011; Nitti, 2006; Patel et al., 2006; Sahai et al., 2009; Tincello et al., 2014).

Efficacy.

RCTs have documented the clinical effects of onabotulinumtoxinA both in NDO and IDO, wherein the drug decreases incontinence episodes, frequency, and urgency and improves QoL (Andersson et al., 2017; Dmochowski et al., 2010a; Mangera et al., 2011; Sahai et al., 2007; Tincello et al., 2012). **The drug was also shown to be effective in patients with OAB** (Andersson et al., 2017; Nitti et al., 2013b). **Successful OAB treatment with BoNTA does not appear to be related to the existence of DO.** No differences in outcomes were found between those with and those without baseline DO (Kanagarajah et al., 2012; Rovner et al., 2011). Nitti et al. (2013b) reported results of the first large (N = 557) phase III placebo-controlled trial of onabotulinumtoxinA in OAB patients. To be included, patients had three or more UUI episodes in 3 days and eight or more micturitions per day. They were randomized 1 : 1 to receive an intradetrusor injection of onabotulinumtoxinA 100 units or placebo (saline). Coprimary end points were change from baseline in UI episodes per day and proportion of patients with a positive response on the treatment benefit scale (TBS) at week 12 after treatment. Secondary end points included other OAB symptoms and health-related QoL. OnabotulinumtoxinA significantly reduced the daily frequency of UI episodes versus placebo (−2.65 vs. −0.87; $P < .001$), and 22.9% versus 6.5% of patients became completely continent. A larger proportion of onabotulinumtoxinA-treated patients than those receiving placebo reported a positive response on the TBS (60.8% vs. 29.2%; $P < .001$). All other

OAB symptoms improved versus placebo ($P \leq .05$). OnabotulinumtoxinA improved patients' health-related QoL across multiple measures ($P < .001$).

The finding that onabotulinumtoxinA 100 units was consistently effective with a twofold to fourfold improvement over placebo in all symptoms of OAB is important; an effect of this magnitude versus placebo does not seem to have been reported previously with antimuscarinics or β_3-AR agonists.

Adverse Effects.

The most frequent side effects reported after intradetrusor BoNTA injection are bladder pain and urinary infection (Del Popolo et al., 2008; Karsenty et al., 2008; Kuo et al., 2010)**. Hematuria may also occur, most of the times mild in nature. The most dangerous side effect, paralysis of the striated musculature caused by circulatory leakage of the toxin, has never been reported. Transient muscle weakness was, nevertheless, reported with abobotA application in several studies** (Akbar et al., 2007; Del Popolo et al., 2008; Wyndaele and Van Dromme, 2002). Of 199 NDO patients followed for 8 years, 5 developed hyposthenia when injected with abotbotA 1000 units (Del Popolo et al., 2008). In another study with 44 patients, 3 adults also treated with 1000 units developed muscular weakness, which subsided after 5 to 7 weeks (Akbar et al., 2007). No such cases were reported with onabotA (Karsenty et al., 2008). The reason for the lack of transient muscle weakness in BoNTA-treated patients is unclear but might be related to the larger size of its molecule, which limits diffusion into the bloodstream. Caution should be used in selecting high-risk patients for treatment, including children, patients with low pulmonary reserve, and patients with myasthenia gravis. Aminoglycosides should be avoided during BoNTA treatment because they might block motor plates and therefore enhance BoNTA effect.

The most feared complication of BoNTA application in patients with voluntary voiding is urinary retention and a transient necessity to perform CIC. It is therefore strongly recommended that in patients with spontaneous voiding, BoNTA administration be preceded by a complete discussion of information regarding this risk. Caregivers should ideally teach CIC to each patient before toxin injection. In the study by Nitti et al. (2013a), the majority of adverse effects occurred in the first 12 weeks (15.5% with onabotA vs. 5.9% with placebo). The most frequently reported adverse effect was uncomplicated urinary tract infection with no upper urinary tract involvement. Other adverse effects were dysuria (12.2%), bacteriuria (5.0%), and urinary retention (5.4%).

PVR urine volume significantly increased with onabotA versus placebo, with the highest volume at week 2 after treatment, and 8.7% of patients had an increase from baseline of 200 mL or more in PVR urine volume at any time after the initial toxin treatment (none with placebo). The proportion of patients who initiated CIC at any time during treatment cycle 1 was 6.1% versus none in the placebo group; for over one-half of the patients who initiated CIC (10 of 17), the duration of CIC was 6 weeks or less. This value is lower than those reported in previous studies on IDO. In the study by Nitti et al. (2013b), discontinuation rates because of adverse effects were low in both the onabotulinumtoxinA (1.8%) and in the placebo (1.4%) groups.

Visco et al. (2012) performed a double-blind, double placebo-controlled, randomized trial (the ABC trial) in women with idiopathic UUI. The participants were randomly assigned for a 6-month period to daily oral antimuscarinic medication (solifenacin, 5 mg initially, with possible escalation to 10 mg and, if necessary, subsequent switch to trospium ER, 60 mg) plus one intradetrusor injection of saline or one intradetrusor injection of 100 units of onabotulinumtoxinA plus daily oral placebo. The authors concluded that oral antimuscarinic therapy and onabotulinumtoxinA by injection were associated with similar reductions in the frequency of daily episodes of UUI. The group receiving onabotulinumtoxinA was less likely to have dry mouth and more likely to have complete resolution of UUI but had higher rates of transient urinary retention and urinary tract infections.

Capsaicin and Resiniferatoxin (Vanilloids).

There is a rationale for the use of intravesical vanilloids (capsaicin and resiniferatoxin [RTX]) to suppress DO and urgency without DO. Results have not been consistent, and practical application has been a hurdle.

Rationale for Intravesical Vanilloids.

The rationale for intravesical vanilloid application in patients with DO is the demonstration that capsaicin, following bladder C-fiber desensitization, suppresses involuntary detrusor contractions dependent on a sacral micturition reflex (de Groat, 1997). The C-fiber micturition reflex is usually inactive, but it was shown that it is enhanced in patients with chronic spinal cord lesions above sacral segments (de Groat, 1997) in those with chronic BOO (Chai et al., 1998) and in those with IDO (Silva et al., 2002). In the bladders of NDO patients, the enhancement of the micturition reflex is accompanied by an increase in the number of suburothelial C-fibers expressing TRPV1 (Brady et al., 2004a). It is curious that NDO patients who responded better to intravesical RTX exhibited a significant decrease in the density of TRPV1 immunoreactive fibers, whereas nonresponders experienced a nonsignificant variation (Brady et al., 2004a). A decrease in TRPV1 expression in urothelial cells of NDO patients was also demonstrated after intravesical application of RTX (Apostolidis et al., 2005a, 2005b, 2006).

Changes in suburothelial C-fiber innervation expressing neuropeptides (Smet et al., 1997) or TRPV1 (Liu and Kuo, 2007) were also reported in patients with sensory urgency. In IDO patients, responders to intravesical RTX are closely associated with the overexpression of the receptor in the bladder mucosa (Liu and Kuo, 2007). In women with sensory urgency, TRPV1 mRNA expressed in trigonal mucosa was not only increased but also inversely correlated with the bladder volume at first sensation of filling during cystometry, further indicating that TRPV1 may play a role in premature bladder sensation (Liu et al., 2007).

Intravesical Capsaicin.

Intravesical capsaicin for NDO was studied in six noncontrolled (Cruz et al., 1997; Das et al., 1996; De Ridder et al., 1997; Fowler et al., 1992b, 1994; Geirsson et al., 1995) and one controlled (de Sèze et al., 1998) clinical trial. Capsaicin was dissolved in 30% alcohol, and 100 to 125 mL (or half of the bladder capacity if lower than that volume) of 1- to 2-mM solutions were instilled into the bladder and left in contact with the mucosa for 30 minutes. The Best clinical results were found in patients with incomplete spinal cord lesions, in whom clinical improvement could be observed in up to 70% to 90% (Cruz et al., 1997; De Ridder et al., 1997; Fowler et al., 1994). In patients with complete spinal cord lesions, the success rate was much lower (Geirsson et al., 1995).

Only one small RCT compared capsaicin against 30% ethanol, the vehicle solution. Ten patients received capsaicin; a significant regression of the incontinence and urge sensation was found. In contrast, only 1 of the 10 patients who received ethanol had clinical improvement (de Sèze et al., 1998).

The pungency of alcoholic capsaicin solutions has prevented the widespread use of this compound. In particular, the possibility of triggering autonomic dysreflexia with capsaicin, especially in patients with higher spinal cord lesions, has progressively restrained its use. The relevance of capsaicin might, however, be back, with a recent report by de Sèze et al. (2006), who used a new capsaicin formulation. They conducted a double-blind placebo-controlled study with a glucidic solution of capsaicin in 33 NDO patients. The glucidic capsaicin–treated group showed improvement both in symptoms and in urodynamic parameters above the comparator arm. The global tolerance of this new capsaicin formulation was excellent (de Sèze et al., 2006).

Resiniferatoxin in Neurogenic Detrusor Overactivity.

RTX has the **advantage over capsaicin in being much less pungent** (Cruz et al., 1997). Intravesical RTX application in NDO patients was evaluated in five small open-label studies (Cruz et al., 1997; Kuo, 2003; Lazzeri et al., 1997, 1998; Silva et al., 2000). Different RTX concentrations, 10 nM, 50 nM, 100 nM, and 10 µM, were tested. RTX brought a rapid improvement or disappearance of UI in up to 80% of the selected patients and a 30% decrease in their daily urinary frequency. Furthermore, RTX also increased the volume to FDC and maximal cystometric capacity. In general, in patients receiving 50- or 100-nM RTX, the effect was long-lasting, with a duration of more than 6 months being reported. In patients treated with 10-µM doses, transient urinary retention sometimes occurred (Lazzeri et al., 1998).

In a placebo-controlled study, the urodynamic effects of RTX in NDO patients were specifically evaluated. Only in the RTX arm, a significant increase in FDC and maximal cystometric capacity was found (Silva et al., 2005). RTX also caused a significant improvement in urinary frequency and incontinence (Silva et al., 2005).

RTX 600 nM was compared against BoNTA (Botox, 300 units) in a study involving 25 patients with NDO from chronic SCI. Both neurotoxins were capable of significantly reducing the number of daily incontinence episodes and improving maximum bladder capacity, although BoNTA turned out to be more effective.

Resiniferatoxin in Idiopathic Detrusor Overactivity.

The first study with intravesical RTX in IDO patients was designed as a proof-of-concept study and involved 13 patients. Intravesical RTX 50 nmol/L was associated with an improvement in volume to FDC from 170 ± 109 mL to 440 ± 153 mL at 30 days, and to 391 ± 165 mL at 90 days. An increase in mean MCC from 291 ± 160 mL to 472 ± 139 mL at 30 days and to 413 ± 153 mL at 90 days was also observed. These improvements were accompanied by a decrease in episodes of urgency incontinence and of daily frequency (Silva et al., 2002). Subsequent small open-label studies confirmed these observations using either a single high dose (50 to 100 nM) or multiple low doses (10 nM) (Dinis et al., 2004; Kuo, 2003, 2005b).

The effect of RTX on refractory IDO was evaluated in two randomized clinical trials (Kuo et al., 2006; Rios et al., 2007). Kuo et al. (2006) randomized 54 patients to receive four weekly instillations of a low-concentration RTX solution (10 nmol/L) or the vehicle solution, 10% ethanol in saline (Kuo et al., 2006). Three months after completing the four intravesical treatments, the RTX-treated group had 42.3% and 19.2% of patients feeling much better or improved, respectively. This was significantly more than in the placebo group—14.2% and 7.1%, respectively. At 6 months, treatment remained effective in 50% of patients in the RTX group but only in 11% in the placebo group (Kuo et al., 2006). Such clinical and urodynamic findings could not be reproduced in another study in which patients were randomly assigned to receive a single intravesical dose of 100 mL of either RTX 50 nM or placebo. Patients were followed for only 4 weeks. During this period a single 50-nM intravesical dose of RTX was not better than placebo for the treatment of women with IDO and urgency incontinence (Rios et al., 2007).

Resiniferatoxin and Urgency.

The involvement of bladder C fibers in IDO has led some investigators to explore the role of these sensory afferents in the genesis of urgency. In a noncontrolled study involving 12 male patients with LUTS associated with BPH, mean IPSS halved after intravesical administration of RTX (50 nmol/L). The decrease in IPSS was largely the result of improvements in scores related to urgency, in addition to improvement in nocturia and frequency (Dinis et al., 2005). In another open-label study, 15 patients with intractable urgency and frequency, with or without urgency incontinence or bladder pain or discomfort, and without urodynamic evidence of DO received one single administration of 50-nM RTX solution. A trend toward an improvement of urgency was noticed (Apostolidis et al., 2006).

In a quasi-randomized study, 23 OAB patients with refractory urgency entered a 30 day run-in period in which medications influencing the bladder function were interrupted. At the end of this period, patients filled out a 7-day bladder diary. Then patients underwent instillation of 100 mL of 10% ethanol in saline (vehicle solution), and 30 days later a second 7-day diary was collected. Finally, patients underwent instillation of 100 mL of 50-nM RTX in 10% ethanol in saline, and additional bladder diaries were collected at 1 and 3 months. After vehicle instillation, the mean number of episodes of urgency per week was 56 ± 11. At 1 and 3 months after RTX instillation, the number of episodes of urgency decreased to 39 ± 9 ($P = .002$) and 37 ± 6 ($P = .02$), respectively (Silva et al., 2007).

Key Points: Toxins for Overactive Bladder

- Intradetrusor injections of onabotulinumtoxinA have been shown to be effective in the treatment of NDO and IDO and OAB symptoms without DO. The mechanism of action seems to be through both efferent and afferent decreases in the release of transmitter(s) substance(s). The doses used are different for neurogenic and idiopathic conditions. A potential complication in patients with voluntary voiding is urinary retention, and all such patients should be informed of this risk.
- There is a definite rationale for the use of intravesical capsaicin and RTX (vanilloids) for the treatment of patients with DO. Alcoholic capsaicin solution is extremely irritating, and RTX is much less pungent. There have been positive clinical trials with RTX, although some negative results occur as well. At the present time, this is not commonly used.

Estrogens for Urgency Urinary Incontinence and Overactive Bladder Symptoms

Estrogen has been used to treat postmenopausal urgency and urgency incontinence for many years, but there have been few controlled trials to confirm that it is of benefit (Hextall, 2000). A double-blind multicenter study of 64 postmenopausal women with “urge syndrome” failed to show efficacy (Cardozo et al., 1998). All women underwent pretreatment urodynamic investigation to ensure that they had either “sensory” urgency or DO. They were randomized to treatment with oral estriol 3 mg daily or placebo for 3 months. Compliance with therapy was confirmed by a significant improvement in the maturation index of vaginal epithelial cells in the active but not the placebo group. Estriol produced subjective and objective improvements in urinary symptoms but was not significantly better than placebo.

Another RCT from the same group using 25-mg estradiol implants confirmed the previous findings (Rufford et al., 2003) and furthermore found a high complication rate in the estradiol-treated patients (vaginal bleeding).

Symptoms of OAB increase in prevalence with increasing age, and LUTS and recurrent urinary tract infections are commonly associated with urogenital atrophy. Although the evidence supporting the use of estrogens in LUT dysfunction remains controversial, there are considerable data to support their use in urogenital atrophy, and the vaginal route of administration correlates with better symptom relief by improvement in vaginal dryness, pruritus, and dyspareunia, greater improvement in cytologic findings, and higher serum estradiol levels (Cardozo et al., 1998). Overall, vaginal estradiol has been found to be the most effective in reducing patient symptoms, although conjugated estrogens produced the most extensive cytologic change and the greatest increase in serum estradiol and estrone. Suckling et al. (2003) reported the most recent meta-analysis of intravaginal estrogen treatment in the management of urogenital atrophy. Overall, 16 trials including 2129 women were analyzed, and intravaginal estrogen was found to be superior to placebo in terms of efficacy, although there were no differences among types of formulation. Fourteen trials compared safety among the different vaginal preparations and found a higher risk for endometrial stimulation with conjugated equine estrogens (CEEs) as compared with estradiol.

Thus, theoretically there could be a role for combination treatment with an antimuscarinic agent and vaginal estrogen in postmenopausal women. However, the two clinical trials that have been reported to date differ in their outcomes. Tseng et al. (2009) showed superior efficacy in terms of symptom improvement for OAB when tolterodine was used with vaginal estrogen cream as opposed to tolterodine alone. However, Serati et al. (2009) found no difference between tolterodine with or without topical estrogen in women with symptomatic DO.

Evidence Regarding Estrogens and Incontinence From Large Clinical Trials.

The Heart and Estrogen/Progestin Replacement Study (HERS) included 763 postmenopausal women younger than 80 years of age with CHD and intact uteri (Grady et al., 2001). **It was designed to evaluate the use of estrogen in secondary prevention of cardiac events. In a secondary analysis, 1525 participants who reported at least one episode of incontinence per week at baseline were included.** Participants were randomly assigned to 0.625 mg of conjugated estrogens plus 2.5 mg of medroxyprogesterone acetate (MPA) in one tablet (*n* = 768) or placebo (*n* = 757) and were followed for a mean of 4.1 years.

Severity of incontinence was classified as improved, unchanged, or worsened. The results showed that incontinence improved in 26% of the women assigned to placebo compared with 21% assigned to hormones, whereas 27% of the placebo group worsened compared with 39% of the hormone group (*P* = .001). This difference was evident by 4 months of treatment, for both UUI and SUI. The number of incontinence episodes per week increased an average of 0.7 in the hormone group and decreased by 0.1 in the placebo group (*P* < .001). The authors concluded that **daily oral estrogen plus progestogen therapy was associated with worsening UI in older postmenopausal women with weekly incontinence and did not recommend this therapy for treatment of incontinence.** However, it is possible that the progestogen component may have had an influence on the results of this study.

The **Women's Health Initiative (WHI)** was a multicenter double-blind placebo-controlled randomized clinical trial of **menopausal hormone therapy in 27,347 postmenopausal women 50 to 79 years of age who were enrolled from 1992 to 1998; UI symptoms were known in 23,296 participants at baseline and 1 year** (Hendrix et al., 2005). The women were randomized based on hysterectomy status to active treatment or placebo. Those with a uterus were given 0.625 mg of conjugated equine estrogen (CEE) per day plus 2.5 mg of MPA per day (CEE + MPA), whereas those who had undergone hysterectomy received estrogen alone (CEE). At 1 year, hormone therapy was shown to increase the incidence of all types of UI in women who were continent at baseline. The risk was highest for SUI, followed by mixed UI. The combination of CEE and MPA had no significant effect on development of urge UI, but CEE alone increased the risk. For those women experiencing UI at baseline, frequency of micturition worsened in both active groups. Quantity of UI worsened at 1 year in both active groups. Those women receiving hormone therapy were more likely to report that UI limited their daily activities at 1 year. Thus, based on this secondary analysis of data from a huge study, **CEE alone or in combination with MPA after 1 year of therapy was shown to increase the risk for UI in continent menopausal women and worsen UI in those incontinent at baseline.**

The **Nurses' Health Study** was a biennial postal questionnaire that started in 1976 (Grodstein et al., 2004). In the study, 39,436 postmenopausal women 50 to 75 years of age who reported no urinary leakage at the start of the study were followed up for 4 years to identify incident cases of UI; 5060 women with occasional incontinence and 2495 with frequent incontinence were identified.

The **risk for developing UI was increased in postmenopausal women taking hormones compared with women who had never taken hormones.** After cessation of hormone therapy, there was a decreased risk for incontinence such that 10 years after stopping hormones the risk was identical in women who had and who never had taken hormone therapy.

Cody et al. (2009) performed the most recent meta-analysis of the effect of estrogen therapy on the LUT. This study is notable because the conclusions are starkly different from those drawn from the previous review (Moehrer et al., 2003). Overall, 33 trials were identified, including 19,313 incontinent women (1262 involved in trials of local administration), of whom 9417 received estrogen therapy. **Systemic administration (of unopposed oral estrogens—synthetic equine estrogens and CEEs) resulted in worse incontinence than placebo,** although this was heavily influenced by the size of the WHI study (Hendrix et al., 2005). **With regard to combination therapy, there was a similar worsening effect on incontinence when compared with placebo. There was some evidence suggesting that the use of local estrogen therapy may improve incontinence, and overall there were one to two fewer voids in 24 hours and less frequency and urgency.**

The authors concluded that local estrogen therapy for incontinence may be beneficial, although there was little evidence of long-term effect. The evidence would suggest that systemic hormone replacement using CEEs may make incontinence worse. In addition, they reported that there are too few data to comment reliably on the dose type of estrogen and route of administration.

Estrogen has an important physiologic effect on the female LUT, and its deficiency is an etiologic factor in the pathogenesis of a number of conditions. However, the use of estrogen either alone or in combination with progestogen has yielded poor results. **The current level 1 evidence against the use of estrogen for the treatment of UI comes from studies powered to assess their benefit in the prevention of cardiovascular events,** and therefore the secondary analyses have been based only on self-reported symptoms of urinary leakage without any objective data. Despite this, all of these large RCTs show a worsening of preexisting UI, both SUI and UUI, and an increased new incidence of UI with both estrogen and estrogen plus progestogen. However, the majority of subjects in all of these studies were taking combined equine estrogen, and this may not be representative of all estrogens taken by all routes of administration.

In a systematic review of the effects of estrogens for symptoms suggestive of OAB, the conclusion was that estrogen therapy may be effective in

alleviating OAB symptoms, and that local administration may be the most beneficial route of administration (Cardozo et al., 2004c)**. It is quite possible that the reason for this is that the symptoms of urinary urgency, frequency, and urgency incontinence may be a manifestation of urogenital atrophy in older postmenopausal women rather than a direct effect on the LUT** (Robinson and Cardozo, 2003)**. Although there is good evidence that the symptoms and cytologic changes of urogenital atrophy may be reversed by low-dose (local) vaginal estrogen therapy, there is currently no evidence that estrogens with or without progestogens should be used in the treatment of UI.**

Key Points: Hormones and Urinary Incontinence

- Conclusions reached in a number of studies have been that (1) daily oral estrogen plus progestogen therapy is associated with worsening UI in older postmenopausal women with weekly incontinence and (2) CEE alone or in combination with MPA increases the risk for UI in continent menopausal women and worsens UI in those incontinent at baseline.
- There is some evidence suggesting that local (vaginal) therapy with estrogen may improve OAB symptoms in postmenopausal women, perhaps by its reversal of urogenital atrophy.

Other Hormones and Desmopressin

Progesterone and progestogens are thought to increase the risk for UI. LUTS, especially SUI, have been reported to increase in the progestogenic phase of the menstrual cycle (Hextall et al., 2001). In similar studies, progesterone has been shown to increase β-AR activity, leading to a decrease in the urethral closure pressure in female dogs (Raz et al., 1973). However, in the WHI there appeared to be no difference whether or not progestin was given in addition to estrogen (Hendrix et al., 2005).

Selective estrogen receptor modulators (SERMs) have been reported to have varying effects. Each of the SERMs has receptor ligand conformations that are unique and have both estrogenic and antiestrogenic effects. In the clinical trials of levormeloxifene, there was a fourfold increase in the incidence of incontinence, leading to cessation of the clinical trial (Hendrix et al., 2001).

However, raloxifene has not been shown to have any effect on UI (Waetjen et al., 2004). There are no reported clinical trials evaluating the effect of androgens and, in particular, testosterone, on UI in women.

Desmopressin.

The endogenous hormone vasopressin (also known as *antidiuretic hormone*) has two main functions: It causes contraction of vascular smooth muscle, and it stimulates water reabsorption in the renal medulla. These functions are mediated by two specific vasopressin receptors, of which there are two major subtypes, namely **the V_1 and V_2 receptors. The V_2 subtype is particularly important for the antidiuretic effects of vasopressin.** A genetic or acquired defect in making and secreting vasopressin leads to central diabetes insipidus, and genetic defects in the gene encoding the V_2 receptor can cause nephrogenic diabetes insipidus (Insel et al., 2007). Accordingly, **decreased vasopressin levels are believed to be important in the pathophysiology of some forms of polyuria, specifically NP,** which can lead to symptoms such as nocturia (Matthiesen et al., 1996; Weiss et al., 2011a). Nocturia is currently defined by the ICS as the complaint that an individual has to wake at night one or more times to void. It is, however, “an underreported, understudied, and infrequently recognized problem in adults” (Weiss et al., 2011b). Nocturia leads to decreased QoL (Kupelian et al., 2011) and has been associated with both increased morbidity and mortality (Kupelian et al., 2012; Nakagawa et al., 2010). Although it remains largely unknown which fraction of patients with nocturia can indeed be explained by too little vasopressin, the presence of NP in the absence of behavioral factors explaining it (such as excessive fluid intake) is usually considered as an indication that a (relative) lack of vasopressin may exist (Bosch and Weiss, 2010; Weiss et al., 2011b).

Based on these considerations, vasopressin-receptor agonists have been used to treat nocturia, both in children and in adults. Desmopressin is the most common vasopressin analogue used to treat nocturia. Desmopressin shows selectivity for antidiuretic over vasopressor effects. It has a more powerful and longer-lasting antidiuretic action than vasopressin. It is available in formulations for oral, parenteral, and nasal administration. It has a fast onset of action, with urine production decreasing within 30 minutes of oral administration (Rittig et al., 1998). Because symptomatic hyponatremia with water intoxication, which is the only serious adverse event reported in children, occurred after intranasal or intravenous administration of desmopressin (Robson et al., 2007; Thumfart et al., 2005; Van de Walle et al., 2010), the FDA and the European Medicines Agency (EMA) removed the indication for the treatment of primary nocturnal enuresis from all intranasal preparations of desmopressin. An oral lyophilisate formulation (MELT) requiring no concomitant fluid intake is currently available. In a recent open-label, randomized, crossover study, desmopressin MELT was shown to have similar levels of efficacy and safety at lower doses than the tablet formulation of desmopressin in children. A recent study confirmed the superior pharmacodynamic characteristics of desmopressin MELT to desmopressin tablets (De Guchtenaere et al., 2011).

Glazener and Evans (2002) comprehensively reviewed the use of desmopressin in children with nocturnal enuresis. These authors evaluated 47 RCTs involving 3448 children, of whom 2210 received desmopressin. According to the analysis, desmopressin was effective relative to placebo in reducing bedwetting; a dose of 20 µg resulted in a reduction of 1.34 wets per night (95% CI 1.11 to 1.57), and children were more likely to become dry with desmopressin (98%) than with placebo (81%). However, there was no difference between desmopressin and placebo after discontinuation of treatment, indicating that **desmopressin suppresses the symptom of enuresis but does not cure the underlying cause.** In addition, not all children responded sufficiently to desmopressin monotherapy. The combination of desmopressin and an enuresis alarm resulted in a greatly improved short-term success rate and decreased relapse rates (Alloussi et al., 2011). The combination of desmopressin and antimuscarinics resulted in better short- and long-term success rates and a lower relapse rate than desmopressin alone (Alloussi et al., 2009; Austin et al., 2008). For nonresponders to desmopressin, replacement of desmopressin with other medications such as tricyclic antidepressants or loop diuretics could be of benefit, whereas muscarinic-receptor antagonists may be ineffective in such children (De Guchtenaere et al., 2007; Neveus and Tullus, 2008).

Other studies have explored a possible treatment role for desmopressin in the treatment of nocturia in adults. A search for these studies in Medline using the terms *desmopressin* and *nocturia* was performed and limited to clinical studies of de novo nocturia, that is, those that excluded subjects in whom childhood enuresis persisted into adulthood. Several previous studies investigated the use of desmopressin for the treatment of nocturia in the context of multiple sclerosis (Eckford et al., 1994, 1995). One study with single-dose administration reported a reduction in NP, but by design did not assess nocturia (Eckford et al., 1995). Three placebo-controlled, double-blind studies with small patient numbers (16 to

33 patients total per study) reported a significant reduction in nocturia (Eckford et al., 1994; Hilton et al., 1983; Valiquette et al., 1996). Other controlled studies of similar size, most with a crossover design, used micturition frequency within the first 6 hours after desmopressin administration rather than nocturia as their primary end point. These studies consistently reported that desmopressin treatment for up to 2 weeks was efficacious (Fredrikson, 1996; Hoverd and Fowler, 1998; Kinn and Larsson, 1990). Although desmopressin treatment was generally well tolerated, 4 of 17 patients in one study discontinued treatment because of asymptomatic or minimally symptomatic hyponatremia (Valiquette et al., 1996). Accordingly, **desmopressin is now registered for the treatment of nocturia in multiple sclerosis patients** (Cvetkovic and Plosker, 2005). In a small open-label study, desmopressin was also reported to reduce NP in SCI patients (Zahariou et al., 2007).

Further studies have explored the use of desmopressin in adults with nocturia in the apparent absence of neurologic damage. The recruited patient populations were based on different criteria, including having at least two nocturia episodes per night or having NP. Earlier studies mostly used a desmopressin dose of 20 µg given either orally (Asplund et al., 1999) or intranasally (Cannon et al., 1999; Hilton and Stanton, 1982), and tended to be very small (25 or fewer patients). Later studies, as part of the NOCTUPUS program, were considerably larger, involving a total of 1003 screened patients, and higher oral doses (0.1 to 0.4 mg) were administered for a period of 3 weeks of double-blind treatment in adults (Lose et al., 2004; Mattiasson et al., 2002; van Kerrebroeck et al., 2007). A total of 632 patients entered the dose-titration phase, and 422 patients entered the double-blind phase of the three NOCTUPUS trials. To counter the argument that the study was performed in desmopressin responders after the dose-titration phase, all patients in the NOCTUPUS trials were washed out after the dose-titration phase, and to be randomized the patients were required to be returned to baseline nocturnal diuresis before inclusion in the double-blind phase. The trials showed that oral desmopressin (0.1, 0.2, or 0.4 mg) is effective in both men and women 18 years of age or older with nocturia. The number of nocturnal voids decreased from 3 to 1.7 in the desmopressin group compared with 3.2 to 2.7 in the placebo group. In women, the number of nocturnal voids in the desmopressin group decreased from 2.92 to 1.61, whereas that in the placebo group decreased from 2.91 to 2.36. When clinical response was defined as 50% or greater reduction in nocturnal voids from baseline, 34% of men experienced clinical response with desmopressin, compared with 3% of men who received placebo.

In women, 46% of desmopressin-treated patients experienced a clinical response, compared with 7% of patients on placebo.

The efficacy of desmopressin for the treatment of nocturia was confirmed in a long-term (10 to 12 months) open-label study involving 249 patients, which was an extension of the randomized studies in known desmopressin responders. However, a rebound effect was seen when treatment was withdrawn, confirming the association between continued treatment and response (Lose et al., 2004). An open-label pilot study in a nursing home setting also reported that desmopressin had beneficial effects (Johnson et al., 2006).

Around 75% of community-dwelling men and women with nocturia (two or more voids per night) have NP (Rembratt et al., 2003; Swithinbank et al., 2004). The key urologic factors most relevant to nocturia are NP and OAB in women (Irwin et al., 2008) and NP and BPH in men. About 74% of women with OAB have nocturia, and 62% of patients with OAB and nocturia have NP. Among men with nocturia, 83% have NP, 20% have NP alone, and 63% have NP in combination with another factor such as a small nocturnal bladder capacity or BOO (Chang et al., 2006). Therefore, desmopressin combination therapy with α_1-AR antagonists and/or antimuscarinics should be considered for patients with treatment-resistant nocturia. Seventy-three percent of α_1-AR antagonist–resistant BPH patients experienced a 50% or greater reduction in nocturnal voids with oral desmopressin (Yoong et al., 2005). A randomized, double-blind, placebo-controlled study evaluating the long-term (1, 3, 6, and 12 months) efficacy and safety of low-dose (0.1 mg) oral desmopressin in elderly patients (≥65 years of age) reported that low-dose oral desmopressin led to a significant reduction in the number of nocturnal voids and nocturnal urine volume in patients with BPH (Wang et al., 2011).

Because nocturia can be caused by different factors, several studies have investigated whether desmopressin may be beneficial in patients with other symptoms in addition to nocturia. In a small, nonrandomized pilot study of men believed to have BPH, desmopressin was reported not only to improve nocturia, but also to reduce the overall IPSS (Chancellor et al., 1999). An exploratory, placebo-controlled, double-blind study in women with daytime UI reported that intranasal administration of 40 µg of desmopressin increased the number of leakage-free episodes 4 hours after drug administration (Robinson et al., 2004). One double-blind, placebo-controlled pilot study in patients with OAB treated with 0.2 mg of oral desmopressin reported a reduction in voids along with an improvement in QoL (Hashim et al., 2009). Although these data indicate that desmopressin may be effective in treating LUT dysfunction not limited to nocturia, they are too sparse to allow treatment recommendations.

Desmopressin was well tolerated in all the studies and resulted in significant improvements compared with placebo in reducing nocturnal voids and increasing the hours of undisturbed sleep. There was also an improvement in QoL. However, one of the main clinically important side effects of desmopressin use is hyponatremia. Hyponatremia can lead to a variety of adverse events ranging from mild headache, anorexia, nausea, and vomiting to loss of consciousness, seizures, and death. Hyponatremia usually occurs soon after treatment is initiated. **The risk for hyponatremia appears to increase with age, cardiac disease, and increasing 24-hour urine volume** (Rembratt et al., 2006). Based on a meta-analysis, the incidence is around 7.6% (Weatherall, 2004). **Increased age and female gender are well-known risk factors** for the development of desmopressin-induced hyponatremia. Bae et al. (2007) assessed the effects of long-term oral desmopressin on serum sodium and baseline antidiuretic hormone secretion in 15 elderly male patients with severe nocturia (more than three voids nightly) who did not show hyponatremia within 7 days of administration of 0.2 mg desmopressin. Desmopressin (0.2 mg) was administered orally nightly for 1 year. Before and 1 month after the 1-year medication, 24-hour circadian studies were performed to monitor changes in antidiuretic hormone. Every 3 months during the 1-year medication period, serum changes and timed urine chemistry were monitored. The results showed that long-term desmopressin administration gradually decreased serum sodium and induced statistically, but not clinically significant, hyponatremia after 6 months of treatment. Administration of desmopressin for 1 year did not affect baseline antidiuretic hormone secretion. The authors recommended that for long-term desmopressin administration, serum sodium should be assessed regularly, at least every 6 months.

A recent focus has been on exploring gender differences in the antidiuretic response to desmopressin. Juul et al. (2011) found an increasing incidence of hyponatremia with increasing dose, and **at the highest dose level of 100 µg, decreases in serum sodium were approximately twofold greater in women older than 50 years of age than in men.** The gender difference could not be explained by pharmacokinetic differences. They calculated an ED_{50} ratio for men/women to be 2.7 (1.3 to 8.1). A new dose recommendation stratified by gender was suggested in the treatment of nocturia: For men, 50 to 100 µg MELT was suggested to be an efficacious and safe dose, and for women a dose of 25 µg

MELT was recommended as efficacious with no observed incidences of hyponatremia. Weiss et al. investigated the efficacy and safety of 50 and 75 mcg of desmopressin orally disintegrating tablets in 385 men with nocturia. They showed that both doses increased the time to first void from baseline by approximately 40 minutes compared with placebo. The response to desmopressin was seen within 1 week of treatment and was sustained producing significant increases in health-related QoL and sleep quality compared with placebo. Only two subjects 74 and 79 years of age developed hyponatremia (Weiss et al., 2013). A similar study carried out in women explored the efficacy and safety of 25 mcg of desmopressin orally disintegrating tablets compared with placebo. In this study, 261 women with nocturia were randomized to either 25 mcg of desmopressin or placebo. Desmopressin significantly reduced the mean number of nocturnal voids compared with placebo and increased the mean time to first nocturnal void by 49 minutes compared with placebo. Once again, response was seen within the first week of treatment and sustained throughout the 3-month trial. Desmopressin was well tolerated with only three transient decreases in serum sodium level (Sand et al., 2013).

Initiation of desmopressin is currently not indicated for patients 65 years of age and older. The mechanisms behind desmopressin-induced hyponatremia are well understood, and **serum sodium monitoring at baseline and early during treatment of older patients for whom treatment with desmopressin is indicated can greatly reduce their risk for developing the condition.** Other advice regarding treatment administration, such as restriction of evening fluid intake and adherence to the recommended administration regimen, should be followed to minimize the risk for hyponatremia (Vande Walle et al., 2007).

Desmopressin is **useful for patients with nocturia and for children with nocturnal enuresis.** The drug has been proven to be well tolerated and effective in several randomized, placebo-controlled trials and is **recommended as a first-line treatment (either as monotherapy or in combination with other agents)** with proper precaution for patients who have been appropriately evaluated and whose nocturia is related to NP, whether or not this is accompanied by BPH or OAB. For assessment, see Table 120.3. A rapid-acting, quickly metabolized preparation with minimal risk for hyponatremia would obviously be useful for the treatment of nocturia in adults and could have application for “spot usage” for a limited period in patients with OAB.

Key Points: Desmopressin in Nocturnal Polyuria

- Desmopressin is an analogue of vasopressin that shows selectivity for antidiuretic effects (water reabsorption in the renal medulla) over vasopressor effects. It suppresses the symptom of nocturnal enuresis in children without curing the underlying cause. It has been used in a number of studies in patients with and without neurogenic disease for the treatment of nocturia. Results in general have been statistically significant improvements in nocturnal voids and hours of undisturbed sleep.
- The most important adverse event is hyponatremia, an increased risk for which is seen with age, female gender, cardiac disease, and increased 24-hour urine volume. Some regimen of serum sodium monitoring is indicated along with other advice designed to minimize the risk for hyponatremia.

Drug Treatment of Overactivity in Augmented or Intestinal Neobladders

With regard to the subject of overactivity in augmented bowel or intestinal neobladders, Andersson et al. (1992) reviewed this subject and its pharmacologic treatment. They noted a few instances of positive results with drugs given systematically, but locally applied agents were believed to offer more promise. Pure antimuscarinic agents had produced few good results, either locally or systemically. Oxybutynin had shown some good results with local therapy but poor results with systemic therapy. The α- and β-AR agonists had shown little or no effects. Other possibilities mentioned included opioid agonists (diphenoxylate and loperamide), calcium antagonists, potassium channel openers, and NO donors. Apostolidis et al. (2007) reported a case of successful treatment with botulinum toxin A after failed augmentation ileocystoplasty.

Future Possibilities

Peripherally Acting Drugs

Vitamin D_3-Receptor Analogues.

It is well known that vitamin D affects skeletal muscle strength and functional efficiency, and vitamin D insufficiency has been associated with notable muscle weakness. The levator ani and coccygeus skeletal muscles are critical components of the pelvic floor and may be affected by vitamin D nutritional status. Weakened pelvic floor musculature is thought to be associated with the development of UI and fecal incontinence symptoms. Aging women are at increased risk for both pelvic floor dysfunction and vitamin D insufficiency; to date, only small case reports and observational studies have shown an association between insufficient vitamin D and pelvic floor dysfunction symptom severity (Parker-Autry et al., 2012). Rat and human bladders were shown to express receptors for vitamin D (Crescioli et al., 2005), which makes it conceivable that the bladder may also be a target for vitamin D. Analogues of vitamin D_3 have also been shown to inhibit BPH cell proliferation and to counteract the mitogenic activity of potent growth factors for BPH cells (Crescioli et al., 2002, 2003, 2004). Experiments in rats with bladder outflow obstruction (Schröder et al., 2006) showed that one of the analogues, BXL-628, at nonhypercalcemic doses did not prevent bladder hypertrophy, but reduced the decrease in contractility of the bladder smooth muscle that occurred with increasing bladder weight (Schröder et al., 2006). The mechanism of action for the effects has not been clarified. However, elocalcitol was shown to have an inhibitory effect on the RhoA/Rho-kinase pathway (Morelli et al., 2007). Upregulation of his pathway has been associated with bladder changes associated with diabetes, outflow obstruction, and DO (Peters et al., 2006; Christ and Andersson, 2007). In rats with outflow obstruction, previous elocalcitol treatment improved the effects of tolterodine on bladder compliance (Streng et al., 2012). It was suggested that in rats, elocalcitol exerted additional beneficial actions on outflow obstruction–induced functional changes during the filling phase of micturition. If this finding is valid in humans, combined therapy with the drug would be of value.

The effect of elocalcitol on prostate volume was evaluated in patients with BPH, and it was found that elocalcitol was able to arrest prostate growth within 12 weeks in men 50 years of age and older with prostatic volume of 40 mL or greater (Colli et al., 2006). In an RCT enrolling 120 female patients with OAB in which the primary end point was an increase in MVV, a significant increase versus placebo (22% vs. 11%) was demonstrated (Colli et al., 2007). **The determination of whether or not vitamin D–receptor agonism (monotherapy or in combination) will be a useful alternative for the treatment of LUTS and OAB requires further RCTs. However, currently the development of the drug seems to be stopped** (Tiwari, 2009).

Transient Receptor Potential Channel Antagonists.

The **TRP channel superfamily has been shown to be involved in nociception and mechanosensory transduction in various organ systems,** and studies of the LUT have indicated that several TRP channels, including TRPV1, TRPV2, TRPV4, TRPM8, and TRPA1, are expressed in the bladder and may act as sensors of stretch and/or chemical irritation (Andersson et al., 2010a; Araki et al., 2008, 2011; Avelino et al., 2013; Deruyver et al., 2015; Everaerts et al., 2008; Franken et al., 2014). **TRPV1 and TRPV4 channels have been found to be expressed in the urinary bladder** (Birder et al., 2001; Gevaert et al., 2007; Tominaga et al., 1998). TRPV1 is present and active both in the urothelium and in the nerve fibers of several species including humans (Charrua et al., 2009b; Ji et al., 2002). TRPV4 was initially described in the urothelium of rodents and humans (Janssen et al., 2011). Coexpression of the two receptors was observed in 20% of rat urothelial cells (Kullmann et al., 2009). Recent observations indicate, however, that TRPV4 may also be expressed in bladder afferents. In fact, about 30% of L6 dorsal root ganglia neurons that project to the urinary bladder coexpress TRPV1 and TRPV4 (Cao et al., 2009). The physiologic meaning of this observation is unclear.

TRPV1 KO mice have a normal or quasi-normal phenotype. In awake animals, the only change detected in TRPV1 KO mice was a smaller volume per void when compared with wild-type (WT) controls (Birder et al., 2001). In cystometries performed under anesthesia, the TRPV1 KO mice phenotype seems also very benign. Some studies reported that these animals have totally normal cystometric traces (Charrua et al., 2007). However, other studies showed that TRPV1 KO mice develop a few nonvoiding contractions preceding the voiding contraction (Birder et al., 2001; Frias et al., 2012). Accordingly, TRPV1 antagonists (GRC-6211) did not show any relevant effect on bladder activity of intact rodents (Charrua et al., 2009a). In contrast with TRPV1 KO mice, the micturition phenotype of TRPV4 KO animals is clearly abnormal. TRPV4 KO mice are incontinent, most likely because of incomplete bladder emptying (Gevaert et al., 2007). Cystometric studies carried out under physiologic conditions revealed that TRPV4 KO mice have a marked increase in the intercontraction interval when compared with WT littermates (Birder et al., 2002; Gevaert et al., 2007). Likewise, TRPV4 antagonists (HC-067047) decreased the frequency of bladder contractions and increased the intercontraction interval (Everaerts et al., 2010). These observations indicated that TRPV4 has a role in the control of the normal micturition reflex.

Indisputably, TRPV1 and TRPV4 have a role in the increase of micturition frequency associated with cystitis (Charrua et al., 2007; Everaerts et al., 2010). Whereas inflamed WT mice exhibit bladder hyperactivity and intense spinal Fos expression after different forms of bladder inflammation, including acetic acid or bacterial extracts, TRPV1 KO mice have normal cystometries and normal spinal c-Fos expression (Charrua et al., 2007). The same holds true for TRPV4. In fact, TRPV4 KO mice exhibit significantly lower voiding frequencies and larger voided volumes than WT after inflammation with cyclophosphamide (Everaerts et al., 2010).

The blockade of TRPV1 and TRPV4 with specific antagonist confirms the observations carried out in KO animals. As a matter of fact, the TRPV1 antagonist GRC-6211 and the TRPV4 antagonist HC-067047 both abolish the increase of micturition frequency associated with chemical cystitis (Charrua et al., 2009a; Everaerts et al., 2010). Systemic coadministration of TRPV1 and TRPV4 antagonist was more effective in treating the cystitis-induced increase of micturition frequency than the individual application of each antagonist (Avelino et al., 2013). In particular, the effect could be observed at very low doses of the TRPV1 and TRPV4 antagonists, which had no effect when given isolated. This observed effect might be the answer to overcome the eventual adverse events related to the application of some of these antagonists (Planells-Cases et al., 2011). Just to mention a few, TRPV1 antagonists are associated with hyperthermia and increased risk for cardiac ischemia (Avelino et al., 2013), and TRPV4 antagonists may eventually precipitate urinary retention and overflow incontinence (Gevaert et al., 2007).

It has long been known that TRPV1 is involved in the emergence of NDO after spinal cord transection (Avelino and Cruz, 2006). A TRPV1 antagonist, GRC-6211, has been shown to decrease reflex DO in rats after chronic spinal cord transection. With increasing doses, it was possible to obtain a total suppression of bladder activity (Santos-Silva et al., 2012).

Interestingly, Uvin et al. (2015) found evidence for involvement of TRPM8 in rat and mouse models of acute cold-induced urinary urgency.

There seem to be several links between activation of different members of the TRP superfamily and LUTS, DO, and OAB, and further exploration of the involvement of these channels in LUT function, normally and in dysfunction, may be rewarding. However, proof-of-concept studies in humans are still lacking.

Prostanoid-Receptor Agonists and Antagonists.

Developments in the field of prostanoid receptors may open new possibilities for use of selective prostanoid-receptor antagonists for OAB and DO treatment (Aoki et al., 2009; Jones et al., 2009). There is evidence suggesting that PGE_2 contributes to the pathophysiology of OAB and DO: PGE_2 infused into the bladder induces DO in humans and animals and increases PGE_2 production in DO models, and there are high concentrations of PGE_2 in the urine of patients with OAB (McCafferty et al., 2008). PGE_2 is an agonist at EP receptors 1 to 4, all G protein–coupled, which mediate its physiologic effects. Based on studies using KO mice and EP_1-receptor antagonists, it was suggested that the effects of PGE_2 on bladder function were mediated through EP_1 receptors (Schröder et al., 2004). EP receptors can be found on urothelium/suburothelium, in detrusor smooth muscle, and in intramural ganglia (Rahnama'i et al., 2010, 2011; Wang et al., 2008). Functionally, it has been proposed that modulation of bladder activity exerted via EP_1 receptors occurs via an afferent mechanism. Schröder et al. (2004) found no difference in urodynamic parameters between unobstructed EP_1 receptor KO and WT mice. However, EP_1 receptor KO mice did not respond to intravesical PGE_2 instillation, whereas WT mice developed DO. The lack of EP_1 receptor did not prevent bladder hypertrophy caused by partial bladder outflow obstruction, but after obstruction WT mice had pronounced DO, whereas this was negligible in EP_1 receptor KO mice.

Lee et al. (2008b) found that in normal rats a selective EP-receptor antagonist significantly increased bladder capacity, micturition volume, and micturition intervals. The antagonist significantly decreased the stimulatory effects of PGE_2 and decreased the frequency and amplitude of nonvoiding contractions in animals with BOO. It has also been shown that EP_3 receptor KO mice have a diminished response to bladder infusion of PGE_2 and demonstrate an enhanced bladder capacity under basal conditions (Jones et al., 2009). These findings suggest an important contribution for EP_3 receptors in the modulation of bladder function under physiologic conditions and under conditions of enhanced PGE_2 production evoking DO. Thus, EP_1 and EP_3 receptors may have a role in PGE_2-mediated DO.

It is interesting to note that activation of EP_3 receptors evoked diuresis and that EP_3-receptor antagonism was found to induce an antidiuretic effect (Jugus et al., 2009). Thus, to modulate bladder activity, it appears that the EP_3 receptor has a role in regulating urine production. Both effects may be useful for treatment of OAB and DO. It cannot be denied that EP_1 and EP_3 receptors constitute interesting and promising targets for drugs aimed at OAB and DO treatment. However, a randomized, double-blind, placebo-controlled phase II study to investigate the efficacy and safety of the EP_1-receptor antagonist ONO-8539 in patients with OAB syndrome suggests that the role of EP_1-receptor antagonism in the management of the OAB syndrome is minimal (Chapple et al., 2014a).

Intraprostatically Injected Drugs

NX-1207.

NX-1207 is a **new drug under investigation for the treatment of LUTS associated with BPH.** It is a new therapeutic protein of proprietary composition with selective proapoptotic properties (Shore, 2010). The drug is injected directly into the transitional zone of the prostate as a single administration to induce focal cell loss in prostate tissue through apoptosis, leading to nonregressive prostate shrinkage and both short- and long-term symptomatic improvement. Information about the drug is scarce and mostly published in abstract form and not yet in the peer-reviewed literature. Two US phase II trials have been performed (Shore, 2010). One of them was a multicenter, randomized, noninferiority study involving 32 clinical sites with 85 patients and two dose ranges (2.5 and 0.125 mg) and an active open-label comparator (finasteride). Patients and investigators on NX-1207 were double-blind as to dose. The primary end point was change in American Urological Association (AUA) Symptom Index score at 90 and 180 days for a single injection of NX-1207 as compared with finasteride on a noninferiority basis. Inclusion criteria included an AUA symptom score of 15 or higher, diminished peak urine flow (<15 mL/sec), and a prostate size of 30 to 70 mg. The mean AUA symptom score improvement after 90 days in the intent-to-treat group was 9.71 points for 2.5-mg NX-1207 ($n = 48$) versus 4.13 points for finasteride ($n = 24$) ($P = .001$) and 4.29 for 0.125-mg NX-1207 ($n = 7$) ($P = .034$). The 180-day results also were positive (NX-1207 2.5 mg noninferior to open-label finasteride).

No significant changes in serum testosterone or serum prostate-specific antigen (PSA) levels were noted in the NX-1207 cohorts. There were no reported adverse effects on sexual function. Two US multicenter, double-blind, placebo-controlled phase III studies are currently underway. The results of such studies are needed to assess whether or not this therapeutic principle is a useful addition to the current treatment alternatives.

PRX302.

PRX302 is a modified form of proaerolysin, a highly toxic bacterial pore-forming protoxin that requires proteolytic processing by PSA (Singh et al., 2007). The safety and efficacy of PRX302 was evaluated in men with moderate-to-severe BPH (Denmeade et al., 2011). The patients were refractory, intolerant, or unwilling to undergo medical therapies for BPH and had an IPSS higher than 12, a QoL score higher than 3, and prostate volumes of 30 to 80 g. Fifteen patients were enrolled in phase I studies, and 18 patients entered phase II studies. Patients received intraprostatic injection of PRX302 into the right and left transition zone via a transperineal approach in an office-based setting. Phase I subjects received increasing concentrations of PRX302 at a fixed volume; phase II subjects received increasing volumes per deposit at a fixed concentration. IPSS, QoL, prostate volume, Qmax, IIEF score, serum PSA levels, pharmacokinetics, and adverse events were recorded at 30, 60, 90, 180, 270, and 360 days after treatment. Sixty percent of men in the phase I study and 64% of men in the phase II study treated with PRX302 had greater than 30% improvement compared with baseline in IPSS out to day 360. Patients also experienced improvement in QoL and reduction in prostate volume out to day 360. Patients receiving more than 1 mL of PRX302 per deposit had the best response overall. There were no deleterious effects on erectile function. Adverse events were mild to moderate and transient in nature. The major study limitation was the small sample size.

Elhilali et al. (2013) conducted a phase IIb double-blind safety and efficacy evaluation of intraprostatic injection of PRX302 in 92 patients with IPSS of 15 or greater, peak urine flow of 12 mL/sec or less, and prostate volume of 30 to 100 mL. The patients were randomized 2 : 1 to a single ultrasound-guided intraprostatic injection of PRX302 versus vehicle (placebo). It was concluded that PRX302 produced clinically meaningful and statistically significant improvement in patient subjective (IPSS) and quantitative objective (peak urine flow) measures sustained for 12 months.

Cannabinoids.

There is increasing evidence that cannabinoids can influence micturition in animals and in humans, both normally and in bladder dysfunction (Ruggieri, 2011). The effects of the cannabinoids are exerted via two types of well-defined receptors, CB_1 and CB_2, distributed widely in the body. However, additional receptor subtypes cannot be excluded (Pertwee et al., 2010; Ruggieri, 2011). Both in the CNS and in peripheral tissues, CB_1 and CB_2 receptors have been identified; centrally CB_1 and peripherally CB_2 receptors seem to be predominant (Pertwee et al., 2010; Ruggieri, 2011). CB_1 and CB_2 receptors have been identified in all layers of the human bladder (Gratzke et al., 2009; Merriam et al., 2008; Tyagi et al., 2009; Walczak et al., 2009); their expression in the urothelium was found to be significantly higher than in the detrusor, and the expression of CB_1 was higher than that of CB_2 (Tyagi et al., 2009). Gratzke et al. (2009) found higher expression of CB_2 receptors, but not CB_1 receptors, in the mucosa than in the detrusor. Compared with the detrusor, larger amounts of CB_2 receptor–containing nerves that also expressed TRPV1 or CGRP were observed in the suburothelium. Nerve fibers containing CB_2 receptors and VAChT (cholinergic neurons) were located in the detrusor. In general, activation of CB_1 peripherally has been associated with vasodilation and motility changes via suppression of release of neurotransmitters, whereas activation of CB_2 appears to induce anti-inflammatory, antinociceptive, and immunosuppressive actions (Pertwee et al., 2010; Ruggieri, 2011). Several animal studies have suggested a modulatory role of CB_2 receptors in both afferent signaling and cholinergic nerve activity (Gratzke et al., 2009, 2010, 2011). Thus, in vivo, the selective CB_2-receptor agonist, cannabinor, increased micturition intervals and volumes and increased threshold and flow pressures, suggesting that peripheral CB_2 receptors may be involved in sensory functions. In rats with partial urethral obstruction treated daily for 14 days with cannabinor, bladder weight was lower, the ability to empty the bladder was preserved, and nonvoiding contraction frequency was low compared with those in controls.

The key enzyme for the degradation of anandamide and other endogenous cannabinoids is fatty acid amide hydrolase (FAAH). FAAH was found to be expressed in rat and human urothelium and was coexpressed with CB_2 receptors. In rats, an FAAH inhibitor altered urodynamic parameters that reflect sensory functions, suggesting a role for the endocannabinoid system in bladder mechanoafferent functions (Strittmatter et al., 2012).

It has not been established whether the effects of the cannabinoids are exerted in the CNS (brain, spinal cord) or peripherally. In a preliminary report, Blyweert et al. (2003) demonstrated an effect of combined CB_1/CB_2-receptor activation on DO in rats with spinal cord transection, which seemed to exclude the brain as a main site of action.

Clinical experiences with cannabinoid treatment of micturition disturbances including LUTS are limited (Ruggieri, 2011), but both open-label and placebo-controlled studies have demonstrated that orally administered cannabinoid modulators may alleviate neurogenic OAB symptoms refractory to first-line treatment (Brady et al., 2004b; Freeman et al., 2006; Kavia et al., 2010). Brady et al. (2004b) evaluated the efficacy of two whole-plant extracts (Δ^9-tetrahydrocannabinol and cannabidiol) of *Cannabis sativa* in patients with advanced MS and refractory LUTS. Urinary urgency, the number and volume of incontinence episodes, frequency, and nocturia decreased significantly after treatment. Freeman et al. (2006) tested in a subanalysis of a multicenter trial (the Cannabinoids in Multiple Sclerosis [CAMS] study) whether cannabinoids could decrease urgency incontinence episodes without affecting voiding in patients with MS. The CAMS study randomized 630 patients to receive oral administration of the cannabis extract Δ^9-tetrahydrocannabinol or matched placebo. Based on incontinence diaries, a significant decrease in incontinence episodes was demonstrated.

Kavia et al. (2010) assessed the efficacy, tolerability, and safety of Sativex (nabiximols) as an add-on therapy in alleviating bladder symptoms in patients with MS. They performed a 10-week, double-blind, randomized, placebo-controlled, parallel-group trial on 135 randomized subjects with MS and OAB. The primary end point, reduction in daily number of UI episodes from baseline to end of treatment (8 weeks), showed little difference between Sativex and placebo. However, four of seven secondary end points were significantly in favor of Sativex, including number of episodes of nocturia, number of voids per day, and number of daytime voids. The improvement in I-QoL was in favor of Sativex but did not reach statistical significance.

Systemic cannabinoids have effects on the LUT that may have therapeutic potential; local delivery (intravesical, spinal) may be possible, but more information is needed. The mechanisms of cannabinoid receptors in control of the human LUT are incompletely known, and **further research is necessary for the development of novel cannabinoid drugs for treatment of LUT disorders.**

Centrally Acting Drugs.

Many parts of the brain seem to be activated during storage and voiding (Fowler et al., 2008; Griffiths, 2007, 2011; Griffiths and Tadic, 2008), and there is increasing interest in drugs modulating the micturition reflex by a central action (Andersson and Pehrson, 2003). Several drugs used for pain treatment also affect micturition, morphine and some antiepileptic drugs being a few examples. However, **central nervous mechanisms have so far not been preferred targets for drugs aimed to treat OAB, because selective actions may be difficult to achieve.** Holstege (2005), reviewed some of the central mechanisms involved in micturition, including the periaqueductal gray (PAG) and the pontine micturition center (PMC). In this review, Holstege suggested that “the problem in OAB or urgency-incontinence is at the level of the PAG or PMC and their connections, and possible treatments for this condition should target the micturition pathways at that level.”

Gonadotropin-Releasing Hormone Antagonists.

The beneficial effects of the 5α-reductase inhibitors finasteride and dutasteride in the treatment of male LUTS are well documented. The efficacy of other hormonal treatments—for example, antiandrogens or gonadotropin-releasing hormone (GnRH; also known as *luteinizing hormone-releasing hormone* [LHRH]) agonists—is either poor or occurs at the expense of unacceptable side effects such as medical castration associated with hot flushes, decrease of potency and libido, and negative effects on bone density after long-term androgen ablation (Eri and Tveter, 1993; Bosch et al., 1989; Peters and Walsh, 1987; Schroeder et al., 1986). With GnRH antagonists, submaximal noncastrating blockade of the androgen testosterone and consequently of dihydrotestosterone can be achieved, thus avoiding medical castration. Several GnRH antagonists, such as cetrorelix, ozarelix, and teverelix, have been tested in phase IIA/IIB clinical trials for their ability to improve LUTS in patients with BPH (Colli and Tankó, 2010).

In a phase II RCT, Debruyne et al. (2008) demonstrated that the LHRH antagonist cetrorelix, given subcutaneously weekly for 20 weeks to 140 men with LUTS (IPSS ≥13, peak urinary flow rates 5 to 13 mL/sec), rapidly caused a significant improvement in the mean IPSS. The peak decrease was −5.4 to −5.9 versus −2.8 for placebo. All dosage regimens tested were well tolerated, and the authors concluded that the drug offered a safe and effective treatment for male LUTS.

Because of these results, two phase III studies were conducted in the United States and Europe (Æterna Zentaris); in the US study, 637 men were randomized to receive either two doses of placebo or cetrorelix on weeks 2 and 26. The drug showed no statistically significant benefit in improving IPSS. In addition, cetrorelix did not have a significant effect on peak flow rate or prostate volume versus placebo. It is difficult to reconcile this lack of efficacy, given favorable prior results. A subsequent multicenter European trial also failed to show any treatment-related efficacy of cetrorelix. The experience with cetrorelix highlights the importance of randomized, placebo-controlled trials that are appropriately powered to show clinical benefit and safety.

Gabapentin.

Gabapentin is one of the new first-generation antiepileptic drugs that expanded its use into a broad range of neurologic and psychiatric disorders (Striano and Striano, 2008). It was originally designed as an anticonvulsant GABA mimetic capable of crossing the blood-brain barrier (Maneuf et al., 2003). The effects of gabapentin, however, do not appear to be mediated through interaction with GABA receptors, and its **mechanism of action remains controversial** (Maneuf et al., 2003). It has been suggested that it acts by binding to a subunit of the $\alpha_2\delta$ unit of voltage-dependent calcium channels (Gee et al., 1996; Striano and Striano, 2008). Gabapentin is also **widely used not only for seizures and neuropathic pain, but for many other indications, such as anxiety and sleep disorders, because of its apparent lack of toxicity.**

Carbone et al. (2006) reported on the effect of gabapentin on NDO. They found a positive effect on symptoms and significant improvement in urodynamic parameters and suggested that the effects of the drug should be explored in further controlled studies in both NDO and non-neurogenic DO. Kim et al. (2004) studied the effects of gabapentin in patients with OAB and nocturia who were not responding to antimuscarinics. They found that 14 of 31 patients improved with oral gabapentin. The drug was generally well tolerated, and the authors suggested that it can be considered in selective patients when conventional modalities have failed. **It is possible that gabapentin and other $\alpha_2\delta$ ligands (e.g., pregabalin and analogues) will offer new therapeutic alternatives, but convincing RCTs are still lacking.**

Tramadol.

Tramadol is a well-known analgesic drug (Grond and Sablotzki, 2004). By itself,

it is a weak μ-receptor agonist, but it is metabolized to several different compounds, some of them almost as effective as morphine at the μ receptor. However, the drug (metabolites) also inhibits serotonin (5-HT) and noradrenaline reuptake (Grond and Sablotzki, 2004). This profile is of particular interest, because both μ-receptor agonism and amine reuptake inhibition may be useful principles for treatment of LUTS, OAB, and DO, as shown in a placebo-controlled study with duloxetine (Steers et al., 2007).

In rats, tramadol abolished experimentally induced DO caused by cerebral infarction (Pehrson and Andersson, 2003). Tramadol also inhibited DO induced by apomorphine in rats (Pehrson and Andersson, 2003)—a crude model of bladder dysfunction in Parkinson disease. Singh et al. (2008) gave tramadol epidurally and found the drug to increase bladder capacity and compliance and to delay filling sensations without adverse effects on voiding. Safarinejad and Hosseini (2006) evaluated in a double-blind, placebo-controlled, randomized study the efficacy and safety of tramadol in patients with IDO. A total of 76 patients 18 years or older were given 100 mg of tramadol SR every 12 hours for 12 weeks. Clinical evaluation was performed at baseline and every 2 weeks during treatment. Tramadol significantly ($P < .01$) reduced the number of incontinence periods per 24 hours from 3.2 ± 3.3 to 1.6 ± 2.8) and induced improvements in urodynamic parameters. The main adverse event was nausea. It was concluded that in patients with non-neurogenic DO, tramadol provided beneficial clinical and urodynamic effects. **However, the study was later retracted because of unacceptable statistical errors** (Safarinejad and Hosseini, 2006; retracted 2014).

Even if tramadol may not be the most suitable drug for treatment of LUTS and OAB, the **study suggests efficacy for modulation of micturition via the μ receptor.**

NK_1-Receptor Antagonists.

The main endogenous tachykinins—SP, neurokinin A (NKA), and neurokinin B (NKB)—and their preferred receptors—NK_1, NK_2, and NK_3, respectively—have been demonstrated in various CNS regions, including those involved in micturition control (Covenas et al., 2003; Lecci and Maggi, 2001; Saffroy et al., 2003). NK_1 receptor–expressing neurons in the dorsal horn of the spinal cord may play an important role in DO, and tachykinin involvement via NK_1 receptors in the micturition reflex induced by bladder filling has been demonstrated (Ishizuka et al., 1994) in normal rats and, more clearly, rats with bladder hypertrophy secondary to BOO. Capsaicin-induced DO was reduced by blocking NK_1 receptor–expressing neurons in the spinal cord, using intrathecally administered SP-saponin conjugate (Seki et al., 2005). Furthermore, blockade of the spinal NK_1 receptor could suppress detrusor activity induced by dopamine receptor (L-dopa) stimulation (Ishizuka et al., 1995).

In conscious rats undergoing continuous cystometry, antagonists of both NK_1 and NK_2 receptors inhibited micturition, decreasing micturition pressure and increasing bladder capacity at low doses and inducing dribbling incontinence at high doses. This was most conspicuous in animals with outflow obstruction (Gu et al., 2004). Intracerebroventricular administration of NK_1- and NK_2-receptor antagonists to awake rats suppressed detrusor activity induced by dopamine receptor (L-dopa) stimulation (Ishizuka et al., 2000). Taken together, available information suggests that spinal and supraspinal NK_1 and NK_2 receptors may be involved in micturition control.

Aprepitant, an NK_1-receptor antagonist used for treatment of chemotherapy-induced nausea and vomiting (Massaro and Lenz, 2005), significantly improved symptoms of OAB in postmenopausal women with a history of urgency incontinence or mixed incontinence (with predominantly UUI), as shown in a well-designed pilot RCT (Green et al., 2006). The primary end point was percent change from baseline in average daily micturitions assessed by a voiding diary. Secondary end points included average daily total UI and urgency incontinence episodes and urgency episodes. Aprepitant significantly ($P < .003$) decreased the average daily number of micturitions (−1.3 ± 1.9) compared with placebo (−0.4 ± 1.7) at 8 weeks. The average daily number of urgency episodes was also significantly ($P < .047$) reduced (−23.2 ± 32%) compared with placebo (−9.3 ± 40%), and so were the average daily number of urgency incontinence and total UI episodes, although the difference was not statistically significant. In general, aprepitant was well tolerated and the incidence of side effects, including dry mouth, was low.

Since this initial proof-of-concept study suggested that NK_1-receptor antagonism holds promise as a potential treatment approach for OAB symptoms, a randomized, double-blind, multicenter trial enrolled 557 adults with OAB (eight or more average daily micturitions and one or more daily urgency incontinence episodes) (Frenkl et al., 2010). After a 1-week placebo run-in, the patients were randomized to treatment with 8 weeks of daily 0.25-, 1-, or 4-mg serlopitant; 4-mg tolterodine ER; or placebo. Patients kept 7-day voiding diaries. The primary end point was change from baseline in micturitions per day. Secondary end points included urgency, total incontinence, urgency incontinence episodes, and incidence of dry mouth. Of the 557 patients randomized, 476 completed the trial and had valid efficacy data for analysis. Mean change from baseline in daily micturitions was significantly greater for 0.25-mg (−1.1) and 4-mg (−1.1) serlopitant and for tolterodine (−1.5) than for placebo (−0.5), but not for 1-mg serlopitant (−0.8). No serlopitant dose response was demonstrated. Tolterodine was numerically superior to all doses of serlopitant in mean micturitions per day and secondary end points. The incidence of dry mouth on serlopitant (3.3%) was comparable to that on placebo (4.6%) and lower than tolterodine (8.8%). Serlopitant was generally well tolerated.

Haab et al. (2014) performed a phase II, multicenter, double-blind study in which adults with OAB symptoms for longer than 6 months were randomized to receive one of three doses of netupitant (50, 100, or 200 mg) or placebo once daily for 8 weeks. The primary efficacy end point was percentage change from baseline in average number of daily micturitions at week 8. UI, UUI, and urgency episodes were also assessed. They found that the primary efficacy end point was similar in the treatment groups (–13.85 for placebo to –16.17 in the netupitant 200-mg group), with no statistically significant differences between netupitant and placebo.

NK_1-receptor antagonists may have a role in the treatment of OAB, but at least the compounds tested so far do not offer advantages in efficacy compared with tolterodine.

A different approach, modulation of neuropeptide release rather than NK-receptor blockade, was tested in a pilot study with cizolirtine, which is an SP and CGRP release modulator at the spinal cord level. The modulation of SP and CGRP is probably related to the increase in extracellular levels of NA and serotonin. Cizolirtine 200 and 400 mg were compared with placebo in 79 OAB patients. Although the decrease in key OAB symptoms was significantly higher in the active arms, adverse events were reported in 68% and 81% of the patients on cizolirtine 200 and 400 mg, respectively. More commonly reported side effects were gastrointestinal in nature, including dry mouth and dizziness (Martínez-García et al., 2009).

Key Points: Overactive Bladder Mechanisms and

Targets

- There are a number of possibilities, mostly based on theoretic mechanisms of action and studies in experimental animals, for drugs to favorably affect the symptoms of OAB and NDO or IDO.
- These mechanisms, at both the central and the peripheral levels, are intriguing, but with the possible exception of drugs directed at prostate bulk or internal organization, none have achieved consistent clinical success.

Increasing Outlet Resistance

Many factors seem to be involved in the pathogenesis of SUI: urethral support, vesical neck function, and function of the nerves and musculature of the bladder, urethra, and pelvic floor (Chapple and Milsom, 2012; DeLancey, 1997; Koelbl et al., 2009; Mostwin et al., 2005). **Anatomic factors cannot be treated pharmacologically. However, women with SUI have lower resting urethral pressures than age-matched continent women** (Henriksson et al., 1979; Hilton et al., 1983)**, and because it seems likely that there is a reduced urethral closure pressure in most women with SUI, it seems logical to increase urethral pressure to improve the condition.**

Factors that may contribute to urethral closure include tone of urethral smooth and striated muscle and the passive properties of the urethral lamina propria, in particular its vasculature. The relative contribution to intraurethral pressure of these factors is still subject to debate. However, there is ample pharmacologic evidence that a substantial part of urethral tone is mediated through stimulation of α-ARs in the urethral smooth muscle by released NA (Andersson, 1993; Andersson and Wein, 2004). A contributing factor to SUI, mainly in elderly women with lack of estrogen, may be lack of mucosal function. **The pharmacologic treatment of SUI aims at increasing intraurethral closure forces by increasing the tone in the urethral smooth and striated muscles. Several drugs may contribute to such an increase** (Andersson, 1988; Zinner et al., 2004), but relative lack of efficacy and/or side effects have limited their clinical use. For assessments, see Table 120.4.

Drugs Used for Treatment of Stress Incontinence in Women

Estrogens

Estrogens and the Continence Mechanism.

The estrogen-sensitive tissues of the bladder, urethra, and pelvic floor all play an important role in the continence mechanism. For women to remain continent, the urethral pressure must exceed the intravesical pressure at all times except during micturition. **The urethra has four estrogen-sensitive functional layers, all of which have a role in the maintenance of a positive urethral pressure: (1) epithelium, (2) vasculature, (3) connective tissue, and (4) muscle.**

Two types of estrogen receptors (α and β) have been identified in the trigone of the bladder, urethra, and vagina, and in the levator ani muscles and fascia and ligaments within the pelvic floor (Copas et al., 2001; Gebhardt et al., 2001; Smith et al., 1990). After menopause, estrogen receptor α has been shown to vary depending on exogenous estrogen therapy (Fu et al., 2003). In addition, exogenous estrogens affect the remodeling of collagen in the urogenital tissues, resulting in a reduction of the total collagen concentration with a decrease in the cross-linking of collagen in both continent and incontinent women (Falconer et al., 1998; Keane et al., 1997). Studies in both animals and humans have shown that estrogens also increase vascularity in the periurethral plexus, which can be measured as vascular pulsations on urethral pressure profilometry (Endo et al., 2000; Robinson et al., 1996; Versi and Cardozo, 1986).

Estrogens for Stress Urinary Incontinence.

The role of estrogen in the treatment of SUI has been controversial despite a number of reported clinical trials (Hextall, 2000). Some have given promising results, but this may have been because they were small observational studies and not randomized, blinded, or controlled. The situation is further complicated by the fact that a number of different types of estrogen have been used with varying doses, routes of administration, and durations of treatment.

Fantl et al. (1996) treated 83 hypoestrogenic women with urodynamic stress incontinence and/or DO with CEEs 0.625 mg and medroxyprogesterone 10 mg cyclically for 3 months. Controls received placebo tablets. At the end of the study period, the clinical and QoL variables had not changed significantly in either group. Jackson et al. (1996) treated 57 postmenopausal women with urodynamic stress or mixed incontinence with estradiol 2 mg or placebo daily for 6 months. There was no significant change in objective outcome measures, although both the active and placebo groups reported subjective benefit.

Two meta-analyses of early data have been performed. In the first, a report by the Hormones and Urogenital Therapy (HUT) Committee, the use of estrogens to treat all causes of incontinence in postmenopausal women was examined (Fantl et al., 1994). Of 166 articles identified, which were published in English from 1969 to 1992, only 6 were controlled trials and 17 were uncontrolled series. **The results showed that there was a significant subjective improvement for all patients and those with urodynamic stress incontinence. However, assessment of the objective parameters revealed that there was no change in the volume of urine lost;** maximum urethral closure pressure increased significantly, but this result was influenced by only one study showing a large effect.

In the **second meta-analysis,** Sultana and Walters (1990) reviewed 8 controlled and 14 uncontrolled prospective trials and included all types of estrogen treatment. They also found that **estrogen therapy was not an efficacious treatment for SUI** but may be useful for the often associated symptoms of urgency and frequency. **Estrogen when given alone therefore does not appear to be an effective treatment for SUI.**

Several studies have shown that estrogen may have a role in combination with other therapies—for example, α-adrenoceptor agonists. However, phenylpropanolamine (the most widely used α-adrenoceptor agonist in clinical practice) has now been restricted or banned by the FDA.

In a randomized trial, Ishiko et al. (2001) compared the effects of the combination of pelvic floor exercise (PFE) and estriol (1 mg/day) in 66 patients with postmenopausal SUI. Efficacy was evaluated every 3 months based on stress scores obtained from a questionnaire. They found a significant decrease in stress score in mild and moderate stress-incontinent patients in both groups 3 months after the start of therapy and concluded that combination therapy with estriol plus PFE was effective and could be used as first-line treatment for mild SUI. Unfortunately, this has not been reproduced in other clinical trials.

Thus, even before the more recently reported secondary analyses of HERS (Grady et al., 2001) **and WHI** (Hendrix et al., 2005)**, it was already recognized that estrogen therapy had little effect in the management of urodynamic stress incontinence** (Al-Badr et al., 2003; Robinson and Cardozo, 2003).

α-AR Agonists.

Several drugs with agonistic effects on peripheral α-ARs have been used in the treatment of SUI. Relatively recently, a central role of NA has been discovered in increasing the excitability of urethral rhabdosphincter motor neurons in the rat analog of the Onuf nucleus, an effect caused at least in part by α_1-AR–dependent depolarization. This could contribute to the mechanism by which NA reuptake inhibitors improve SUI (Yashiro et al., 2010). **Ephedrine and norephedrine (phenylpropanolamine [PPA]) seem to have been the most widely used** (Andersson and Wein, 2012). The original AHCPR guidelines reported eight RCTs with PPA, 50 mg twice daily for SUI in women (AHCPR, 1992). Percent cures (all figures refer to percent effect in patients on drug minus percent effect in patients on placebo) were listed as 0% to 14%; percent reduction in continence as 19% to 60%; and percent side effects and percent dropouts as 5% to 33% and 0% to 4.3%, respectively. **The most recent Cochrane review on the subject** (Alhasso et al., 2005, reprinted virtually unchanged in 2008) **assessed randomized or quasi- RCTs in adults with SUI** that included an adrenergic agonist drug in at least one arm of the trial. There were no controlled studies reported on the use of such drugs in men. Twenty-two eligible trials were identified, 11 of which were crossover trials, which included 1099 women, 673 of whom received an adrenergic drug (PPA in 11, midrodrine in 2, norepinephrine in 3, clenbuterol in 3, terbutaline in 1, eskornade in 1, and RO 115-1240 in 1). The authors concluded that “there was **weak evidence to suggest that use of an adrenergic agonist was better than placebo in reducing the number of pad changes and incontinence episodes, and improving subjective symptoms.”** There was not enough evidence to evaluate the merits of an adrenergic agonist compared with estrogen, whether used alone or in combination. Regarding adverse events, the review reported similar numbers with adrenergic, placebo, or alternative drug treatment. Over 25% of subjects reported such effects, but when these consisted of effects resulting from adrenergic stimulation, they caused discontinuation in only 4% of the total.

Ephedrine and PPA lack selectivity for urethral α-ARs and can increase blood pressure and cause sleep disturbances, headache, tremor, and palpitations (Andersson and Wein, 2012). Kernan et al. (2000) reported the risk for hemorrhagic stroke to be 16 times higher in women younger than 50 years of age who had been taking PPA as an appetite suppressant (statistically significant) and 3 times higher in women who had been taking the drug for less than 24 hours as a cold remedy (not statistically significant). There was no increased risk in men. PPA has been removed from the market in the United States. It is still allowed as a treatment for SUI in a few countries. Numerous case reports of adverse reactions caused by ephedra alkaloids exist, and some suggested that sale of these compounds as a dietary supplement be restricted or banned (Bent et al., 2003). In December 2003, the FDA decreed such a ban, a move which has survived legal appeal.

Midodrine and methoxamine stimulate α_1-ARs with some degree of selectivity. According to the RCTs available, the effectiveness of these drugs is moderate at best, and the clinical usefulness seems to be limited by adverse effects (Alhasso et al., 2003; Radley et al., 2001; Weil et al., 1998).

Attempts to develop agonists with relative selectivity for the human urethra continue. Musselman et al. (2004) reported on a phase II randomized crossover study with Ro 115-1240, a peripherally active selective $\alpha_{1A/1L}$-AR partial agonist (Blue et al., 2004), in 37 women with mild-to-moderate SUI (Musselman et al., 2004). A moderate, positive effect was demonstrated, but side effects have apparently curtailed further development of the drug. PF-3774076, a CNS-penetrating partial α_{1A}-AR agonist, increased peak urethral pressure in dogs and was selective with respect to α_{1B} and α_{1D} receptors, but HR and blood pressure changes caused significant concern (Conlon et al., 2009). Furuta et al. (2009) reported that the α_2-AR can inhibit the release of glutamate presynaptically in the spinal cord and proposed that α_2-AR antagonists would be useful as a treatment for SUI. This hypothesis awaits testing.

β-AR Agonists

Clenbuterol.

β-AR stimulation is generally conceded to decrease urethral pressure (Andersson, 1993), but β_2-AR agonists have been reported to increase the contractility of some fast-contracting striated muscle fibers and suppress that of slow-contracting fibers of others (Fellenius et al., 1980). Some β-AR agonists also stimulate skeletal muscle hypertrophy—in fast-twitch more than slow-twitch fibers (Kim and Sainz, 1992). Clenbuterol has been reported to potentiate the field stimulation–induced contraction in rabbit isolated periurethral muscle preparations, an action that is suppressed by propranolol and greater than that produced by isoproterenol (Kishimoto et al., 1991). These authors were first to report an increase in urethral pressure with clinical use of clenbuterol and to speculate on its potential for the treatment of SUI. Yamanishi et al. (1994) reported an inotropic effect of clenbuterol and terbutaline on the fatigued striated urethral sphincter of dogs, abolished by β-AR blockade.

Yasuda et al. (1993) described the results of a double-blind placebo-controlled trial with this agent in 165 women with SUI. Positive statistical significance was achieved for subjective evaluation of incontinence frequency, pad use per day, and overall global assessment. Pad weight decreased from 11.7 ± 17.9 g to 6.0 ± 12.3 g for drug and from 18.3 ± 29.0 g to 12.6 ± 24.7 g for placebo, raising questions about the comparability of the two groups. The “significant” increase in maximal urethral closure pressure (MUCP) was from 46.0 ± 18.2 cm H_2O to 49.3 ± 19.1 cm H_2O, versus a change of −1.5 cm H_2O in the placebo group. Fifty-six of 77 patients in the clenbuterol group reported some degree of improvement versus 48 of 88 in the placebo group. The positive effects were suggested to be a result of an action on urethral striated muscle and/or the pelvic floor muscles. Ishiko et al. (2000) investigated the effects of clenbuterol on 61 female patients with stress incontinence in a 12-week randomized study, comparing drug therapy and PFEs. The frequency and volume of stress incontinence and the patient's own impression were used as the basis for the assessment of efficacy. The improvement in incontinence was 76.9%, 52.6%, and 89.5% in the respective groups. In an open study, Noguchi et al. (1997) reported positive results with clenbuterol (20 mg bid for 1 month) in 9 of 14 patients with mild-to-moderate stress incontinence after radical prostatectomy (RP). **Further well-designed RCTs investigating the effects of clenbuterol are needed to adequately assess its potential as a treatment for stress incontinence.**

β-AR Antagonists.

The theoretic basis for the use of β-AR antagonists in the treatment of stress incontinence is that blockade of urethral β-ARs may enhance the effects of NA on urethral α-ARs. Propranolol has been reported to have beneficial effects in the treatment of stress incontinence (Gleason et al., 1974; Kaisary, 1984), but there are no RCTs supporting such an action. In the study by Gleason et al., the beneficial effects manifest only after 4 to 10 weeks of treatment, a phenomenon that is difficult to explain (Gleason et al., 1974). Donker and Van der Sluis (1976) reported that β-blockade did not change the urethral pressure profile in normal women. Although suggested as an alternative to α-AR agonists in patients with SUI and hypertension, these agents may have major potential cardiac and pulmonary side effects of their own, related to their therapeutic β-AR blockade.

Serotonin-Noradrenaline Uptake Inhibitors

Imipramine.

Imipramine, among several other pharmacologic effects, has classically been reported to inhibit the reuptake of NA and serotonin in adrenergic nerve endings. In the urethra, this could theoretically be expected to enhance the contractile effects of NA on urethral smooth muscle by both a peripheral and a central action. Gilja et al. (1984) reported in an open study on 30 women with stress incontinence that imipramine, 75 mg daily, produced subjective continence in 21 patients and increased mean MUCP from 34 to 48 mm Hg. A 35% cure rate was reported by pad test and, in an additional 25%, a 50% or more improvement. Lin et al. (1999) assessed the efficacy of imipramine (25 mg of imipramine three times a day for 3 months) as a treatment for genuine stress incontinence in 40 women with genuine stress incontinence. A 20-minute pad test, uroflowmetry, filling and voiding cystometry, and stress urethral pressure profile were performed before and after treatment. The efficacy of "successful treatment" was 60% (95% CI 11.8 to 75.2). **There are no RCTs on the effects of imipramine on SUI.** No subsequent published reports have appeared.

It is interesting to note that Gillman (2007) reported that clomipramine had far greater 5-HT reuptake inhibition than imipramine and roughly similar NA reuptake inhibition. Desipramine and reboxetine had greater NA reuptake inhibition (desipramine superior), with lesser effect than imipramine on 5-HT uptake (desipramine superior).

Duloxetine.

Duloxetine hydrochloride is a combined norepinephrine and serotonin reuptake inhibitor that has been shown to significantly increase sphincteric muscle activity during the filling and storage phase of micturition in the cat acetic acid model of irritated bladder function (Katofiasc et al., 2002; Thor and Katofiasc, 1995). Bladder capacity was also increased in this model, with both effects mediated centrally through both motor efferent and sensory afferent modulation (Fraser et al., 2003). The sphincteric effects were reversed by α_1-adrenergic antagonism (prazosin) and 5-HT_2 serotonergic antagonism (LY-53857), whereas the bladder effects were mediated by temporal prolongation of the actions of serotonin and norepinephrine in the synaptic cleft (Fraser et al., 2003). Duloxetine is lipophilic, well absorbed, and extensively metabolized (CYP2D6). Its plasma half-life is approximately 12 hours (Sharma et al., 2000).

Thor et al. (2007) described the mechanisms of action and the physiologic effects of duloxetine. 5-HT (serotonin) and NA terminals are dense in spinal areas associated with LUT functioning, especially around the pudendal nerve neurons in the Onuf nucleus. These are projections from separate areas in the brainstem. Glutamate is the primary excitatory neurotransmitter in the spinal cord, activating the pudendal neurons in the Onuf nucleus, causing contraction of the urethral rhabdosphincter. The rhabdosphincter innervation is proposed as distinct from that of the levator ani (Thor and de Groat, 2010). The responsiveness of the rhabdosphincter motor neurons to glutamate is modulated (facilitated) by 5-HT (through 5-HT_2 receptors) and NA (through α_1-ARs). 5-HT and NA, however, only modulate, and, when micturition occurs, glutamate excitation and rhabdosphincter contraction cease. Excitatory effects on urethral sphincter activity are shared to a lesser extent by receptors for 5-HT_{1A} (indirect through a supraspinal stimulation), thyrotropin-releasing hormone vasopressin, *N*-methyl-ᴅ-aspartate (NMDA), and AMPA; inhibitory effects are similarly mediated by κ_2 opioid receptors, α_1-ARs, and GABA-A, GABA-B, and glycine receptors (Thor and de Groat, 2010). Some CNS-penetrant selective 5-HT_{2C} agonists have been found to increase urethral muscle tone and inhibit micturition reflexes in animal models, and these are additional candidates for clinical development for the treatment of SUI (Andrews et al., 2011; Brennan et al., 2009).

Several RCTs have documented the effect of duloxetine in SUI (Dmochowski et al., 2003a; Millard and the Asia Pacific Tolterodine Study Group, 2004; Norton et al., 2002; Van Kerrebroeck et al., 2004). **A Cochrane review of the effects of duloxetine for SUI in women is available;** the last substantive amendment is listed as May 25, 2005 (Mariappan et al., 2005). Fifteen reports were deemed eligible for analysis, 9 primary studies and 6 additional reports related to one or two of the primary references. An additional analysis “performed under the auspices of the Cochrane Incontinence Group” was performed on just the nine primary trials comparing duloxetine and placebo, and published separately (Mariappan et al., 2005). The results can be summarized as follows. **Subjective “cure” in the duloxetine 80 mg daily (40 mg bid) group was higher than in the placebo group (10.8% vs. 7.7%,** overall relative risk [RR] 1.42, 95% CI 1.02 to 1.98, $P = .04$). The estimated absolute size of effect was about 3 more patients cured for every 100 treated. **Objective cure data, available from only one trial, showed no clear difference between the drug**

and placebo. Duloxetine showed greater improvement in I-QoL (weighted mean difference for 80 mg 4.5, 95% CI 2.83 to 6.18, $P < .00001$). Adverse effects in six trials were analyzed. These were reported by 71% of drug subjects and 59% of those allocated to placebo. Nausea was the most common adverse event, with an incidence that ranged from 23% to 25%, and was the main reason for discontinuation. Other side effects reported were vomiting, constipation, dry mouth, fatigue, dizziness, and insomnia—overall RR was 1.30 (95% CI 1.23 to 1.37). Across these six trials, 17% in the drug group withdrew, as did 4% in the placebo arm. In the 2007 article, the authors conclude by saying that **further research is needed regarding whether management policies incorporating duloxetine are clinically effective and cost-effective compared with other current minimally invasive and more invasive approaches** in patients with varying severity of SUI, and that "longer term experience is now a priority to determine whether there is sustained efficacy during and after duloxetine use and to rule out complications."

Hurley et al. (2006) characterized the safety of duloxetine for treatment of SUI in women, using an integrated database generated from four published placebo-controlled clinical trials. The database included 1913 women randomized to duloxetine (958) or placebo (955), examining adverse events, serious adverse events, vital signs, ECGs, and laboratory analytes. Adverse events occurring initially or worsening during the double-blind treatment period were considered treatment emergent. Differences between duloxetine-treated and placebo-treated groups were compared statistically. Common TEAEs included nausea (23.2%), dry mouth (13.4%), fatigue (12.7%), insomnia (12.6%), constipation (11.0%), headache (9.7%), dizziness (9.5%), somnolence (6.8%), and diarrhea (5.1%). Most TEAEs that emerged early were mild to moderate, rarely worsened, and resolved quickly. Overall, adverse event discontinuation rates were 20.5% for duloxetine and 3.9% for placebo ($P < .001$). Most discontinuations (83%) occurred within the first month of treatment. Serious adverse events were uncommon and did not differ between treatments. Statistically significant but clinically unimportant mean increases in HR (2.4 beats/min) and systolic and diastolic blood pressure (≤2 mm Hg) occurred. No arrhythmogenic potential was observed, and any rare, transient, asymptomatic increases in hepatocellular enzymes were normalized. The authors concluded that duloxetine was safe and tolerable, although transient adverse events were not uncommon. Hashim and Abrams (2006) suggested that to reduce the risk for nausea, treatment should begin with a dose of 20 mg twice daily for 2 weeks, which should then be increased to the recommended 40-mg bid dose.

Ghoneim et al. (2005) randomized women with SUI to one of four treatment combinations: duloxetine alone (40 mg bid), pelvic floor muscle training (PFMT), combination, and placebo. Overall, drug with or without PFMT was superior to PFMT alone or placebo, whereas pad results and QoL data favored combination therapy over single treatment. Cardozo et al. (2004a) reported that 20% of women awaiting continence surgery changed their minds while taking duloxetine. Duckett et al. (2006) offered a 4-week course to women awaiting a tension-free vaginal tape operation. Thirty-seven percent (of 73) declined. Excluding women for whom concomitant prolapse surgery was planned, 8 of 33 (24%) scheduled for incontinence surgery alone came off the list. Sixteen (48%) discontinued duloxetine because of adverse events, and 9 (27%) found the drug ineffective.

Bent et al. (2008) reported on the effects of 12 weeks of duloxetine (40 mg bid) versus placebo in a large group of women with mixed urinary incontinence (MUI). For SUI episodes, the mean incontinence episode frequency (IEF) per week decreased 58.9% with drug (7.69 to 3.93) versus 43.3% for placebo (8.93 to 6.05). It is interesting to note that corresponding decreases for UUI episodes were 57.7% versus 39.6%. Both sets of values are statistically significant, but the baselines are different and the absolute change for SUI amounted to −3.76 episodes per week for drug and −2.87 for placebo. Nausea was reported by 18% of patients on drug and 4.5% on placebo. Corresponding percents for other adverse events included dry mouth (12 vs. 2.8), dizziness (9.7 vs. 2.4), constipation (8.3 vs. 4.2), and fatigue (6.7 vs. 2.8). Nausea and dizziness were less common in a subgroup taking concurrent antidepressants. In a study by Schagen van Leeuwen et al. (2008), women 65 years of age and older with SUI or stress-predominant MUI (S-MUI) were given duloxetine (40 mg bid after a 2-week start on 20 mg bid) or placebo for 12 weeks. Their report concludes that “this study supports the use of duloxetine in elderly women with SUI or S-MUI.” The data show an absolute change in SUI plus S-MUI episodes of −11.7 and −6.9 incontinence per week (drug and placebo) and median percent changes of −52.5% versus −36.7% from 24-hour diaries, both significant at $P < .001$. However, the changes for SUI alone were −53% versus −42% (nonsignificant), whereas for S-MUI alone they were −51.6% versus −32.7% ($P < .001$). Nausea was less than in other trials (7.5% vs. 3.1%), perhaps because of the lower starting dose. Other adverse events included fatigue (14.2% vs. 5.4%), constipation (10.4% vs. 0.8%), dizziness (9.0% vs. 4.6%), and excess sweating

(5.2% vs. 0%).

Vella et al. (2008) studied persistence on duloxetine and found that only 31% of an original cohort of 228 were still taking the drug beyond 4 weeks, 12% at 4 months, 10% at 6 months, and 9% at 1 year. Fifty-six percent of the discontinuations were attributed to side effects, and 33% were attributed to lack of efficacy. Bump et al. (2008), however, reported that the positive effects of duloxetine were maintained in patients who continued treatment for up to 30 months, but admitted that this subgroup was likely to include predominantly patients who had favorable responses. The number decreased from 1424 in this cohort at 3 months to 368 at 30 months.

Shaban et al. (2010) concluded that duloxetine is an "optional second line for women not willing or unfit for surgery after warning against side effects as recommended by NICE [National Institute for Health and Care Excellence] guidelines in the UK" Robinson and Cardozo (2010) also expressed similar sentiments.

Duloxetine is licensed at 40 mg twice daily for the treatment of SUI in the European Union in women with moderate-to-severe incontinence (defined as 15 or more episodes per week). It was withdrawn from the FDA consideration process in the United States for the treatment of SUI but is approved for the treatment of major depressive disorder (20 to 30 mg bid initially, 60 mg once daily for maintenance), diabetic peripheral neuropathic pain (60 mg once daily), generalized anxiety disorder (60 mg once daily), **fibromyalgia** (30 mg once daily initially, 60 mg once daily for maintenance), and **chronic musculoskeletal pain** (30 mg once daily initially, 60 mg once daily for maintenance. **The product information contains a black box warning** of "increased risk of suicidal thinking and behavior in children, adolescents and young adults taking antidepressants for major depressive disorder and other psychiatric disorders," noting also that "depression and certain other psychiatric disorders are themselves associated with increases in the risk of suicide" (Cymbalta prescribing information, revised 2019). Other warnings and precautions in the prescribing information for psychiatric indications, not SUI, include hepatotoxicity (not to be used in patients with substantial alcohol use or chronic liver disease); orthostatic hypotension; serotonin syndrome (general statement regarding SSRIs and SNRIs); abrupt discontinuation (may result in dizziness, paresthesias, irritability, and headache); inhibitors of CYP1A2 (such as ciprofloxacin) and thioridazine (do not administer concomitantly); and potent inhibitors of CYP2D6 (may increase concentration). Adverse events for 6801 drug- and 4487 placebo-treated patients reported in the prescribing information for Cymbalta (treatment for the indications mentioned) are nausea (24% vs. 8%), dry mouth (13% vs. 5%), fatigue (10% vs. 5%), somnolence (10% vs. 3%), insomnia (10% vs. 6%), constipation (10% vs. 4%), and dizziness (10% vs. 5%).

Drugs Used for Treatment of Stress Urinary Incontinence in Men

Although a problem of significant magnitude, especially after RP for cancer, **the pharmacologic treatment of male SUI is an area that has received relatively little attention.**

Intrinsic sphincter function is the most important outlet factor maintaining continence in men. Urethral support is less important, and there is no entity similar to the hypermobility phenomenon in women. The proximal urethral sphincter extends from the bladder neck through the prostatic urethra. Its function is removed by RP. The distal urethral sphincter includes the rhabdosphincter, urethral smooth muscle, and extrinsic paraurethral skeletal muscle, extending from the prostatic urethra below the verumontanum through the membranous urethra (Koelbl et al., 2009). Tsakiris et al. (2008) searched for articles on drug treatment of male SUI published from 1966 to 2007 and did a generalized database search in addition. Nine trials were identified as using α-adrenergic agonists, β_2 antagonists, or SNRIs. Only one of these included a comparison arm (Filocamo et al., 2007), 40-mg bid duloxetine plus PFE versus PFE with placebo. The results suggested a positive effect of drug but were a bit confusing. Of patients completing the 4-month trial (92 of 112), 78% of the drug-treated patients versus 52% of those in the placebo group were “dry.” However, 1 month after the end of the study, the corresponding figures were 46% versus 73%, a shift still observed 2 months later. The authors of the review article recommended further larger and well-designed studies on duloxetine for this potential use.

Cornu et al. (2011) reported a series of post-RP men with SUI or S-MUI randomized to duloxetine (15) and placebo (16) after a 2-week placebo run-in. The dosage was 20 mg bid for 7 days, 40 mg bid for 67 days, and 20 mg bid for 14 days. Subjects were at least 1 year postsurgery. Outcome measures included percent decrease in IEF, 1-hour pad test, and various QoL measures. Statistical significance for IEF percent decrease occurred only at weeks 8 and 12 ([−]52.2% ± 38.6% vs. [+]19% ± 43.5%), but there was clearly a trend at 4 weeks. There was no statistical difference in 1-hour pad test weights, but there was in various QoL scores. A 50% to 100% decrease in IEF was seen at 12 weeks in over one-half of the patients. Adverse events for drug and placebo included fatigue (50% vs. 13%), insomnia (25% vs. 7%), libido loss (19% vs. 7%), constipation (13% vs. 7%), nausea (13% vs. 7%), diarrhea (13% vs. 7%), dry mouth (6% vs. 0%), anorexia (6% vs. 0%), and sweating (25% vs. 20%). Drawbacks and concerns are the small number (the original proposed sample size was 90) and the lack of any placebo effect on IEF and QoL. There were four men with MUI in the drug group and five in the placebo group. Results for SUI and UUI were not separated.

One would logically not expect improvement to continue after drug withdrawal unless a permanent change occurred in behavior, anatomy, or neuromuscular function. In another uncontrolled use study on men with post-RP SUI, Collado Serra et al. (2011) reported on 68 men whose median interval from surgery was 28.8 months. The reported results are somewhat confusing, but the overall impression is that some success was achieved. Treatment was intended to last for 9 months and restarted at 3 months if UI had worsened after cessation. The follow-up examinations were performed every 3 months, evaluating the symptoms, adverse effects, number of pads used daily, and International Consultation on Incontinence Questionnaire Urinary Incontinence Short Form (ICIQ-IU-SF) results. At the end of the first follow-up period, 39 (57%) of 68 patients had reduced the number of pads used daily. The pads per day nadir was achieved at the second follow-up visit in 29 (43%) of 68 patients, in 3 (8%) of 37 at the third visit, and in 2 (12%) of 17 at the fourth visit. Once the nadir of success with treatment had been reached, the efficiency of duloxetine was maintained in 84% of patients and worsened in 16% despite continuing treatment. In this study, 25% of patients withdrew because of adverse events and 33% because of lack of effect.

Usage of duloxetine for SUI in men is universally off-label. A drug for this indication would be welcome. **Larger, controlled, and better-designed studies are necessary to provide conclusive positive or negative data on this subject.**

Key Points: Drugs for Stress Urinary Incontinence

- Pharmacologic efforts to increase outlet resistance in men and women have focused on increasing urethral tone or contractile ability at a peripheral or central level.

- The role of estrogen in the treatment of SUI has been somewhat controversial; however, the majority opinion seems to be that estrogen when given alone does not appear to be an effective treatment for SUI in the woman.
- The use of peripheral α_1-AR agonists has largely been abandoned because of the adverse effects associated with these agents and the weak evidence of efficacy compared with placebo.
- Paradoxically, there are theoretic rationales for using both β-AR agonists and antagonists for treatment of SUI, but there are few data suggesting significant efficacy over control, and further well-designed randomized clinical trials are necessary.
- Duloxetine is a combined norepinephrine and serotonin reuptake inhibitor that increased sphincteric activity in an animal experimental model during the filling and storage phase of micturition. This compound has been widely tried in a variety of situations and using a variety of parameters. Some trials suggest statistical efficacy, more so in subjective data than objective data, and further research is needed regarding whether management policies incorporating this compound are clinically effective and cost-effective compared with other current approaches in women with varying degrees of SUI. Currently, duloxetine is licensed in the European Union for women with moderate-to-severe stress incontinence. It is approved in the United States for treatment of a variety of disorders, but was withdrawn from the approval process for the treatment of SUI.
- Effective pharmacologic management of SUI in men would be a welcome addition to the armamentarium, but this has received relatively little attention. There are a few clinical trials with interesting experimental designs and results, and it is obvious that larger, controlled, and better-designed studies are necessary to provide conclusive positive or negative data. The use of duloxetine for SUI in men is universally off-label.

Pharmacologic Therapy to Facilitate Bladder Emptying

Increasing Intravesical Pressure and Bladder Contractility

Parasympathomimetic Agents

Because a major portion of the final common pathway in physiologic bladder contraction is stimulation of parasympathetic postganglionic muscarinic cholinergic receptor sites, agents that imitate the actions of ACh might be expected to be effective in treating patients who cannot empty the bladder because of inadequate bladder contractility. ACh, **which is a quaternary amine,** cannot be used for therapeutic purposes because of its action at both muscarinic and nicotinic receptors; it is rapidly hydrolyzed by acetylcholinesterase and by butyrylcholinesterase (Brown and Taylor, 2006). Many ACh-like drugs exist, but only bethanechol chloride exhibits a relatively selective in vitro action on the urinary bladder and gut with little or no nicotinic action (Brown and Taylor, 2006). **Bethanechol is cholinesterase resistant and causes an in vitro contraction of smooth muscle from all areas of the bladder** (see Chapter 69).

Bethanechol, or agents similar to it, has historically been recommended for the treatment of postoperative or postpartum urinary retention, but only if the patient is awake and alert and if there is no outlet obstruction. The recommended dose has been 5 to 10 mg subcutaneously. For over 50 years, bethanechol has been recommended for the treatment of the atonic or hypotonic bladder and has been reported as effective in achieving "rehabilitation" of the chronically atonic or hypotonic detrusor (Sonda et al., 1979). Bethanechol has also been reported to stimulate or facilitate the development of reflex bladder contractions in patients in spinal shock secondary to suprasacral SCI (Perkash, 1975).

Although bethanechol has been reported to increase gastrointestinal motility and has been used in the treatment of gastroesophageal reflux, and although anecdotal success in specific patients with voiding dysfunction seems to occur, **there was little or no evidence to support its success in facilitating bladder emptying in a series of patients in whom the drug was the only variable** (Barendrecht et al., 2007; Finkbeiner, 1985). In one set of trials, a pharmacologically active subcutaneous dose (5 mg) did not demonstrate significant changes in flow parameters or residual urine volume in (1) a group of women with a residual urine volume greater than or equal to 20% of bladder capacity but no evidence of neurologic disease or outlet obstruction; (2) a group of 27 “normal” women of approximately the same age; or (3) a group of patients with a positive bethanechol supersensitivity test (Wein et al., 1980a, 1980b). This dose did increase cystometric filling pressure and also decreased bladder capacity threshold, findings previously described by others (Sonda et al., 1979). Short-term studies in which the drug was the only variable have usually failed to demonstrate significant efficacy in terms of flow and residual urine volume data (Barrett, 1981). Farrell et al. conducted a double-blind randomized trial that looked at the effects of two catheter-management protocols and the effect of bethanechol on postoperative retention after gynecologic incontinence surgery (Farrell et al., 1990). They concluded that bethanechol was not helpful at all in this setting. Although bethanechol is capable of eliciting an increase in bladder smooth muscle tension, as would be expected from in vitro studies, its ability to stimulate or facilitate a coordinated and sustained physiologic-like bladder contraction in patients with voiding dysfunction has been unimpressive (Andersson, 1988; Finkbeiner, 1985).

It is difficult to find reproducible urodynamic data that support recommendations for the use of bethanechol in any specific category of patients. Most, if not all, “long-term” reports in such patients are neither prospective nor double-blind and do not exclude the effects of other simultaneous regimens (such as treatment of urinary infection, bladder decompression, timed emptying, or other types of treatment affecting the bladder or outlet), an important observation to consider when reporting such drug studies. Whether repeated doses of bethanechol or any cholinergic agonist can achieve a clinical effect that a single dose cannot is speculative, as are suggestions that bethanechol has a different mode of action or effect on atonic or decompensated bladder muscle than on normal tissue.

Bethanechol administered subcutaneously does cause an increased awareness of a distended bladder and presumably the desire to void (Downie, 1984). This could facilitate more frequent emptying at lower volumes and thereby help to avoid overdistention, but, it would seem, only in a bladder that is capable of a contraction. O'Donnell and Hawkins (1993) administered 5 mg of bethanechol subcutaneously to 10 neurologically intact men and made the following cystometric observations: Bladder volume at first desire to void decreased (220 mL to 85 mL), maximal bladder capacity decreased (380 mL to 160 mL), first desire to void occurred at a higher pressure (5 cm H_2O vs. 28 cm H_2O), and compliance was reduced. They concluded that bethanechol affects the ability of the bladder to accommodate volume. Patients were comfortable at a resting bladder pressure of 20 cm H_2O (uncommon in their population), and the pressures at maximal bladder capacity were considerably higher than commonly seen under normal conditions. This suggested to them that either bladder pressure alone is not a significant factor in the perception of a sensation of first desire to void or that bethanechol somehow alters the threshold at which perception of desire to void occurs (because these patients showed a tolerance for increased intravesical pressure before first desire to void and at maximal bladder capacity). De Wachter and Wyndaele (2001) determined the bladder electrical threshold in healthy volunteers receiving 5 mg of bethanechol subcutaneously. They found a marked decrease in the volume at which various filling sensations occurred and that the electrical threshold decreased after drug administration. De Wachter et al. (2003) treated 18 women with impaired detrusor contraction with subcutaneous bethanechol (5 mg four times daily) for 10 days. At the end of treatment, 61% of the patients voided without a PVR volume. They also found that in these women the sensation of filling and the electrical sensitivity were significantly increased compared with before treatment. The authors suggested that patients likely to respond to bethanechol can be identified by determination of the bladder electrical perception threshold.

Riedl et al. (2000) performed a clinical study in 45 patients with detrusor areflexia. The patients were tested with electromotive administration of intravesical bethanechol. Bethanechol 25 mg given orally once daily was then prescribed for 15 patients, and voiding control was assessed after 6 weeks of therapy. A mean pressure increase of 34 cm H_2O during the electromotive administration of bethanechol was found in 24 of 26 patients with areflexia and neurologic disease compared with only 3 cm H_2O in 3 of 11 with a history of chronic bladder dilation. Oral bethanechol restored spontaneous voiding in 9 of 11 patients who had had a positive response to the electromotive administration of bethanechol, whereas all 4 without a pressure increase during the electromotive administration of bethanechol did not void spontaneously. The researchers concluded that electromotive administration of intravesical bethanechol can identify patients with an atonic bladder and adequate residual detrusor muscle function who are candidates for restorative measures, such as oral bethanechol and intravesical electrostimulation. Those who do not respond to the electromotive administration of bethanechol do not benefit from oral bethanechol and are candidates for catheterization.

No agreement exists as to whether cholinergic stimulation produces an increase in urethral resistance (Wein et al., 1980a, 1980b). It would appear that pharmacologically active doses, in fact, do increase urethral closure pressure, at least in patients with NDO (Sporer et al., 1978). This would of course tend to inhibit bladder emptying. As to whether cholinergic agonists can be combined with agents to decrease outlet resistance to facilitate emptying and achieve an additive or synergistic effect, our own experience with such therapy, using even 200 mg (50 mg qid) of oral bethanechol daily, has been disappointing. Certainly, most clinicians would agree that a total divided daily dose of 50 to 100 mg rarely affects any urodynamic parameter at all. In a prospective, single-blind, randomized study consisting of 119 patients with underactive detrusor, Yamanishi et al. (2004) studied the effect of a combination of a cholinergic drug (bethanechol 60 mg daily or distigmine 15 mg daily) and an α-AR antagonist (urapidil 60 mg daily). The effectiveness of each therapy was assessed 4 weeks after initialization of the therapy using IPSS. IPSS remained unchanged after the cholinergic therapy, but was significantly lower after the α-AR antagonist treatment and the combination therapy. With regard to the total IPSS, there were significant differences between the cholinergic and the α-AR antagonist groups, and also between the cholinergic and combination groups, in favor of the latter. The average and maximum flow rates did not increase significantly after monotherapy with either the cholinergic drug or the α-AR antagonist, but they significantly increased after combination therapy compared with baseline values. PVR volume did not decrease significantly after the cholinergic drug therapy but decreased significantly after the α-AR antagonist and the combination therapies. The authors concluded that combination therapy with a cholinergic drug and an α-AR antagonist appeared to be more useful than monotherapy for the treatment of underactive detrusor.

The question of whether bethanechol may be efficacious in a particular patient can be answered by a brief urodynamically controlled trial in which institution of therapy is the only variable. In the laboratory, a functioning micturition reflex is an absolute requirement for the production of a sustained bladder contraction by a subcutaneous injection of the drug (Downie, 1984). **Patients with incomplete lower motor neuron lesions constitute the most reasonable group for a trial of bethanechol** (Awad, 1985), although subcutaneous administration may be required. **It is generally agreed that, at least in a “denervated” bladder, an oral dose of 200 mg is required to produce the same urodynamic effects as a subcutaneous dose of 5 mg** (Diokno and Lapides, 1977).

The **potential side effects of cholinomimetic drugs** include flushing, nausea, vomiting, diarrhea, gastrointestinal cramps, bronchospasm, headache, salivation, sweating, and difficulty with visual accommodation (Brown and Taylor, 2006). Intramuscular and intravenous use can precipitate acute and severe side effects, resulting in acute circulatory failure and cardiac arrest, and are therefore prohibited. Contraindications to the use of this general category of drug include bronchial asthma, peptic ulcer, bowel obstruction, enteritis, recent gastrointestinal surgery, cardiac arrhythmia, hyperthyroidism, and any type of BOO.

One potential avenue of increasing bladder contractility is cholinergic enhancement or augmentation. Such an action might be useful alone or in combination with a parasympathomimetic agent. **Metoclopramide** is a dopamine-receptor antagonist with cholinergic properties (Pasricha et al., 2006). It has a central antiemetic effect in the chemoreceptor trigger zone and peripherally increases the tone of the lower esophageal sphincter, promoting gastric emptying. Its effects seem to be related to its ability to antagonize the inhibitory action of dopamine, to augment ACh release, and to sensitize the muscarinic receptors of gastrointestinal smooth muscle. Some data from dogs suggest that this agent can increase detrusor contractility (Mitchell and Venable, 1985), but there are no controlled studies documenting a useful clinical effect in the treatment of detrusor underactivity.

Cisapride is a substituted piperidinyl benzamide with a number of different pharmacologic activities, including a possible direct stimulation of smooth muscle (Pasricha, 2006). Until recently, it was commonly used as a prokinetic agent, particularly for gastroesophageal reflux and gastroparesis. It was also suggested that it could improve bladder contractility (Binnie et al., 1988; Carone et al., 1993; Steele et al., 2001). However, there was never any particularly convincing data that the drug improved voiding function, and it is no longer available in the United States because of its potential to induce serious and occasional cardiac arrhythmias (Pasricha, 2006). The concept, however, of cholinergic enhancement or augmentation remains attractive but awaits the development of a bladder-selective compound.

Prostaglandins

The reported use of prostaglandins to facilitate emptying is based on hypotheses that these substances contribute to the maintenance of bladder tone and bladder contractile activity (see Chapter 69; Andersson, 1993, 1999a, 1999b, 1999c; Andersson and Wein, 2004; Zderic et al., 1995). **Prostaglandins and thromboxane A_2 (TXA_2) have been shown to be present in human bladder in the following quantitative order: $PGE_2 > PGE_1 > PGF_{2\alpha} > TXA_2$; isolated detrusor muscle is contracted by $PGF_{2\alpha}$, PGE_1, PGE_2, and TXA_2** (see references in Andersson and Wein, 2004). **Prostanoids are synthesized locally in both bladder muscle and mucosa, with synthesis being initiated by various physiologic stimuli such as detrusor muscle stretch, mucosal injury, neural stimulation; by ATP; and by mediators of inflammation** (Andersson and Wein, 2004). Prostanoids may affect bladder activity directly by effects on the smooth muscle or indirectly through effects on neurotransmission. **Possible roles mentioned by Andersson include (1) neuromodulators of efferent and afferent neurotransmission; (2) sensitization or perhaps activation of certain sensory nerves; and (3) potentiation of ACh release from cholinergic nerve terminals through prejunctional prostanoid receptors** (Andersson, 2000b)**. PGE_2 seems to cause a net decrease in urethral smooth muscle tone; $PGF_{2\alpha}$ causes an increase.**

Bultitude et al. (1976) first reported that instillation of 0.5 mg of PGE_2 into the bladders of female patients with varying degrees of urinary retention resulted in acute emptying and in improvement of longer-term emptying (several months) in two-thirds of the patients studied ($N = 22$). Desmond et al. (1980) reported results with intravesical use of 1.5 mg of this agent (diluted with 20 mL of 0.2% neomycin solution) in patients whose bladders exhibited no contractile activity or in whom bladder contractility was relatively impaired. Twenty of 36 patients showed a strongly positive immediate response, and 6 showed a weakly positive one. Fourteen patients were reported to show prolonged beneficial effects, all but 1 of whom had shown a strongly positive immediate response. Stratification of the data revealed that an intact sacral reflex arc was a prerequisite for any type of positive response. Tammela et al. (1987) reported that one intravesical administration of 10 mg of $PGF_{2\alpha}$ facilitated voiding in women who were in retention 3 days after surgery for SUI. The drug was administered in 50 mL of saline solution as a single dose and retained for 2 hours. However, in these “successfully” treated patients, the average maximum flow rate was 10.6 mL/sec with a mean residual urine volume of 107 mL, and the authors stated that “bladder emptying deteriorated in most patients on the day after treatment.” Koonings et al. (1990) reported that daily intravesical $PGF_{2\alpha}$ and intravaginal PGE_2 reduced the number of days required for catheterization after stress incontinence surgery when compared with a control group receiving intravesical saline solution.

Others, however, have reported negative results. Grignaffini and Bazzani (1998) reported on instillation of 1.5 mg of PGE_2 in 50 mL of saline solution into the bladder of 50 patients on their fourth day after vaginal hysterectomy and cystourethropexy, with a control group of 60 patients. The results are presented in an interesting fashion. After catheter removal, after the PGE_2 or control treatment, 58% of the PGE_2-treated group voided spontaneously as compared with 48.3% of the control group. This difference was not significant. Thus 42% of the treated group and 51.7% of the control group were in retention. Of those who were in retention, the number who were in retention for less than 3 days was greater in the PGE_2 group (32%) versus the control group (25%), and this was statistically significant. Likewise, the number who remained in urinary retention for 3 days or longer after the initial treatment was 10% in the PGE_2-treated group versus 26.7% in the control group. Stanton et al. and Delaere et al. reported on success using intravesical PGE_2 in doses similar to those reported earlier (Delaere et al., 1981; Stanton et al., 1979). Delaere et al. (1981) similarly reported no success using $PGF_{2\alpha}$ in a group of women with emptying difficulties of various causes. Wagner et al. (1985) used PGE_2 in doses of 0.75 to 2.25 mg and reported no effect on urinary retention in a group of patients after anterior colporrhaphy.

In a prospective randomized, double-blind study, Hindley et al. (2004) tested the hypothesis that the combination of intravesical PGE_2 and oral bethanechol is additive or synergistic in improving bladder emptying. Nineteen patients with detrusor underactivity (17 men and 2 women) were eligible and randomized to one of two treatments. One group (9 patients) received once-weekly intravesical PGE_2 (1.5 mg in 20 mL of 0.9% saline) plus bethanechol 50 mg four times daily, for a total of 6 weeks. A second group of 10 patients received a once-weekly instillation of saline together with placebo tablets, again for 6 weeks. Although there was evidence of a pharmacologic effect, bethanechol and PGE_2 had a limited therapeutic effect compared with placebo. The authors did not recommend this treatment as routine but suggested that it may be considered for the occasional treatment of a patient with detrusor underactivity.

There has been little recent activity in this area, a fact that usually means that clinicians have lost interest or that the initial optimistic results have not been confirmed. **Prostaglandins have a relatively short half-life, and it is difficult to understand how any effects after a single application can last up to several months. If such does occur, it must be the result of a "triggering effect" on some unknown physiologic or metabolic mechanism. Because of the number of conflicting positive and negative reports with various intravesical preparations, double-blind, placebo-controlled studies would obviously be helpful to see whether there are circumstances in which prostaglandin use can reproducibly facilitate emptying or treat postoperative retention.** Potential systemic side effects of prostaglandin use include vomiting, diarrhea, pyrexia, hypertension, and hypotension (Campbell and Halushka, 1996).

Blockers of Inhibition

de Groat et al. have demonstrated a sympathetic reflex during bladder filling that, at least in the cat, promotes urine storage partly by exerting an α-AR–mediated inhibitory effect on pelvic parasympathetic ganglionic transmission (see Chapter 69; de Groat, 1997; de Groat et al., 1993, 1999; Zderic et al., 1995). Some have suggested that α-AR blockade, in addition to decreasing outlet resistance, may in fact facilitate transmission through these ganglia and thereby enhance bladder contractility. On this basis, Raz and Smith (1976) were first to advocate a trial of an α-AR–blocking agent for the treatment of nonobstructive urinary retention. A complete discussion of postoperative retention, including the use of α-AR antagonists for its treatment, is presented in Chapter 65.

Opioid-Receptor Antagonists

Endogenous opioids have been hypothesized to exert a tonic inhibitory effect on the micturition reflex at various levels (see Chapter 69; Zderic et al., 1995), and agents such as opioid-receptor antagonists therefore may offer possibilities for stimulating reflex bladder activity.

Thor et al. (1983) were able to stimulate a micturition contraction with naloxone, an opioid-receptor antagonist, in unanesthetized cats with chronic SCI.

The effects, however, were transient, and tachyphylaxis developed. Vaidyanathan et al. (1981) reported that an intravenous injection of 0.4 mg of naloxone enhanced detrusor reflex activity in 5 of 7 patients with neuropathic bladder dysfunction caused by incomplete suprasacral spinal cord lesions. The maximum effect occurred within 1 to 2 minutes after intravenous injection and was gone by 5 minutes. Murray and Feneley (1982) reported that the same dose of naloxone caused, in a group of patients with IDO, an increase in detrusor pressure at zero volume and at first desire to void, a decrease in the maximum cystometric capacity, and a worsening of the degree of instability. Galeano et al. (1986) reported that although naloxone increased bladder contractility in cats with chronic spinal injury, it also aggravated DSD and spasticity—a potential problem in the treatment of emptying failure. Wheeler et al. (1987) noted no significant cystometric changes in a group of 15 SCI patients after intravenous naloxone, whereas 11 showed decreased perineal EMG activity. **Although an intriguing area, the concept of reversing an inhibitory opioid influence to stimulate reflex bladder activity is of little practical use at present.**

Key Points: Treatment of Detrusor Underactivity

- A pharmacologic agent that is effective for the treatment of detrusor underactivity or underactive bladder would be welcome. It is difficult to find reproducible urodynamic data that support a recommendation for the use of oral bethanechol chloride in any specific category of patients, despite its pharmacologic characteristics as a cholinergic agonist. It is possible that bethanechol, by increasing static intravesical pressure, may cause afferent stimulation at a lower bladder volume than usual, prompting detrusor contraction at a more favorable bladder volume. Such an action would be expected to occur only in bladders that were not truly acontractile.
- Prostaglandins could theoretically facilitate bladder activity either directly by effects on the smooth muscle or indirectly through effects on neurotransmission or increased sensitization to filling stimuli. Initial reports of the use of intravesical prostanoids producing lasting favorable clinical effects have not been confirmed. Work continues on oral agents.

Decreasing Outlet Resistance

At a Site of Anatomic Obstruction

This topic includes the treatment of BOO secondary to BPE. A full discussion is appropriately included in Chapter 104.

At the Level of the Smooth Sphincter

α-Adrenoceptor Antagonists.

Whether or not one believes that there is significant innervation of the bladder and proximal urethral smooth musculature by postganglionic fibers of the sympathetic nervous system, one must acknowledge the existence of α- and β-AR sites. **The smooth muscle of the bladder base and proximal urethra contains predominantly α-ARs, although β-ARs are present. The bladder body contains both varieties of ARs, with β-ARs (β_3) being more common (see Chapter 69;** Andersson, 2000b; Zderic et al., 1995**). The human LUT contains more α_2- than α_1-ARs, but adrenergically induced prostatic smooth muscle contraction and human LUT smooth muscle contraction are mediated largely, if not exclusively, by α_1-ARs.** There are at least three subtypes of α_1-ARs, designated α_{1A}, α_{1B}, and α_{1D}. **Adrenergically induced smooth muscle contraction in the human LUT is mediated largely by the α_{1A}** (and in the detrusor α_{1D}) subtype (Andersson and Gratzke, 2007; Andersson and Wein, 2004; Docherty, 1998; Harada and Fujimura, 2000; Michel and Vrydag, 2006; Yamada and Ito, 2011). In addition to the three cloned α_1-ARs, there is a possible fourth, α_{1L}, although the α_{1L}-AR is probably a variant of the α_{1A} type. There is a tremendous amount of information and controversy in the literature regarding the selectivity of certain α-AR–blocking agents for these respective receptor subtypes. Conclusions are drawn regarding the "best" α_1-AR antagonist for the treatment of at least BPH on the basis of in vitro and in vivo pharmacologic selectivity, but many authors note that this does not necessarily translate into functional selectivity in a given patient (Andersson, 2002c; Djavan et al., 2004). The various α-AR antagonists are discussed in more detail in Chapter 104.

Krane and Olsson (1973) **were among the first to promote the concept of a physiologic internal sphincter partially controlled by tonic sympathetic stimulation of contraction-mediating α-ARs in the smooth musculature of the bladder neck and proximal urethra. Furthermore, they hypothesized**

that some obstructions at this level during bladder contraction are a result of inadequate opening of the bladder neck and/or of an inadequate decrease in resistance in the area of the proximal urethra. They also theorized and presented evidence that α-AR blockade could be useful in promoting bladder emptying in such a patient with an adequate detrusor contraction but without anatomic obstruction or DSD. They and many others (see Wein and Barrett, 1988) have confirmed the usefulness of α-AR blockade in the treatment of what is now usually referred to as *smooth sphincter* or *bladder neck dyssynergia* or *dysfunction.* Successful results, usually defined as an increase in flow rate, a decrease in residual urine, and an improvement in upper tract appearance (where pathologic), could often be correlated with an objective decrease in urethral profile closure pressure.

One would expect success with such therapy to be most evident in patients without DSD, as reported by Hachen (1980). Mobley (1976), however, reported a startling 86% subjective success rate in 21 patients with a reflex neurogenic bladder, with a corresponding success rate of 66% in what was called “flaccid” and 57% of what was called “autonomous” neurogenic bladder dysfunction, with success being defined as PVR urine volume consistently less than 100 mL. On the other hand, Scott and Morrow (1978) noted excellent results with phenoxybenzamine therapy in 9 of 10 patients with a flaccid bladder and a flaccid external sphincter and in a single patient with an upper motor neuron bladder with intact sympathetic innervation, but in only 8 of 21 patients with hyperreflexia and autonomic dysreflexia, and in none of 6 patients with an upper motor neuron bladder and sympathetic denervation (lesion between T10 and L2).

Although most would agree that α-AR–blocking agents exert their favorable effects on voiding dysfunction by affecting the smooth muscle of the bladder neck and proximal urethra, **information in the literature suggests that they may decrease striated sphincter tone as well,** and other information suggests that they may exert some of their effects on at least the filling and storage symptoms of voiding dysfunction by decreasing bladder contractility (see earlier discussion). Much of the confusion relative to whether α-AR–blocking agents have a direct (as opposed to indirect) inhibitory effect on the striated sphincter relates to the interpretation of clinical observations and experimental data referable to their effect on urethral pressure in the region of the urogenital diaphragm and on electromyographic activity in the periurethral striated muscle of this area. One cannot tell by pressure tracings alone whether decreased resistance in this area of the urethra is secondary to a decrease in smooth or striated muscle activity. Nanninga et al. (1977) found that the electromyographic activity of the external sphincter decreased after phentolamine administration in three paraplegic patients and attributed this effect to a direct inhibition of sympathetic action on the striated sphincter. Nordling et al. (1981) demonstrated that clonidine and phenoxybenzamine (both of which pass the blood-brain barrier) also decreased urethral pressure in this area and yet had no effect on EMG activity. They concluded that (1) the effect of phentolamine was from smooth muscle relaxation alone; (2) the effect of clonidine, and possibly phenoxybenzamine, was elicited mostly through centrally induced changes in striated urethral sphincter tonus; and (3) these agents also had an effect on the smooth muscle component of urethral pressure. None of the three drugs, however, affected the reflex rise in either urethral pressure or electromyographic activity seen during bladder filling, and none decreased the urethral pressure or electromyographic activity response to voluntary contraction of the pelvic floor striated musculature. Gajewski et al. (1984) concluded that α-AR blockers do not influence the pudendal nerve–dependent urethral response in the cat through a peripheral action but that at least prazosin can significantly inhibit this response at a central level. Thind et al. (1992) reported on the effects of prazosin on static urethral sphincter function in 10 healthy women. They found a reduction—predominantly in the midurethral area—and hypothesized that the response was caused by a decrease in both smooth and striated sphincter activity, the latter as a result of reduced somatomotor output from the CNS. Clinically, Chancellor et al. (1994) reported that terazosin, a selective α_1-AR antagonist, had little or no effect on striated sphincter function in SCI patients and had no effect on functional obstruction caused by DSD in these patients.

α-AR blocking agents have also been used to treat both bladder and outlet abnormalities in patients with so-called “autonomous” bladders, such as those with myelodysplasia, sacral spinal cord or infrasacral neural injury, and voiding dysfunction after radical pelvic surgery (Wein and Barrett, 1988). Decreased bladder compliance is a common clinical problem in such patients, and this, along with a fixed urethral sphincter tone, results in the paradoxic occurrence of both storage and emptying failure.

Phenoxybenzamine.

Phenoxybenzamine was the α-AR antagonist originally used for the treatment of voiding dysfunction (Te, 2002). Phenoxybenzamine has **blocking properties at both α_1- and α_2-AR sites.** The initial adult dose of this agent is 10 mg/day, and the usual daily dose for voiding dysfunction is 10 to 20 mg. **After discontinuation, the effects of administration may persist for days, because the drug irreversibly inactivates α-ARs** and the duration of effect depends on the rate of receptor synthesis (Hoffman and Lefkowitz, 1996). Approximately 30% of patients experience side effects (Kirby, 1999). These include orthostatic hypotension, reflex tachycardia, nasal congestion, diarrhea, miosis, sedation, nausea, and vomiting (secondary to local irritation). It has mutagenic activity in the Ames test, and repeated administration to animals can cause peritoneal sarcomas and lung tumors (Westfall and Westfall, 2006). Although this agent has been in clinical use for some 35 years without clinically apparent oncologic associations, one must now consider the potential medicolegal ramifications of long-term therapy, especially in younger persons. Te reassessed the use of phenoxybenzamine for treatment of urinary tract disorders (Te, 2002). It is seldom used at present.

Prazosin.

Prazosin was the first potent selective α_1-AR antagonist (Westfall and Westfall, 2006) used to lower outlet resistance (Andersson et al., 1981). The duration of action is 4 to 6 hours; therapy is usually begun in daily divided doses of 2 to 3 mg. The dose may be very gradually increased to a maximum of 20 mg daily, although seldom has anyone used more than 9 to 10 mg daily for voiding dysfunction. The potential side effects of prazosin are consequent to its α_1-AR blockade. Occasionally, there occurs a “first-dose phenomenon,” a symptom complex of faintness, dizziness, palpitation, and, infrequently, syncope, thought to be caused by acute postural hypotension. The incidence of this can be minimized by restricting the initial dose of the drug to 1 mg and administering this at bedtime. Other side effects associated with chronic prazosin therapy are usually mild and rarely necessitate withdrawal of the drug.

Terazosin and Doxazosin.

Terazosin and doxazosin are two highly selective postsynaptic α_1-AR antagonists. They are readily absorbed with high bioavailability and a long plasma half-life, enabling their activity to be maintained over 24 hours after a single oral dose. Both agents have been evaluated with respect to their efficacy in patients with LUTS and decreased flow rates presumed secondary to BPH. Their efficacy in decreasing symptoms and raising flow rates has been shown to be superior to placebo and similar to that of prazosin (Kirby, 1999; Lepor et al., 2012). Their safety profiles have been well documented as a result of their widespread use over several years for the treatment of hypertension. Side effects are related to peripheral vasodilation (postural hypotension), and both drugs have to be started at a low dose and titrated to obtain an optimum balance between efficacy and tolerability. Dizziness and weakness are sometimes observed, and these are presumed secondary to CNS actions. These drugs are marketed for the treatment of hypertension and LUTS presumed secondary to BPH.

Alfuzosin and Tamsulosin.

Alfuzosin and tamsulosin, both highly selective α_1-AR antagonists, have appeared and are marketed solely for the treatment of BPH because of some reports suggesting preferential action on prostatic rather than vascular smooth muscle (Djavan et al., 2004; Kirby, 1999; Lepor et al., 2012)**. Marketing claims aside, whether there is any difference in the efficacy or side-effect profiles of these individual agents remains a topic of controversy.** Both can be administered once daily and without titration. **Available data suggest that retrograde ejaculation and rhinitis are more common with tamsulosin and silodosin, whereas dizziness and asthenia are more common with terazosin and doxazosin** (Djavan et al., 2004; Kirby et al., 2000; Lepor et al., 2012).

Silodosin.

Silodosin is a novel, highly selective α_{1A}-AR antagonist (Yoshida et al., 2007). Clinical data demonstrated that silodosin showed significant improvement in LUTS associated with BPH, and in QoL (Chapple et al., 2011; Kawabe et al., 2006; Novara et al., 2013). The improvements were observed in both voiding and storage symptoms. Long-term study revealed that the efficacy and safety were sustained for 1 year. The most common adverse event in the silodosin group was abnormal ejaculation, which occurred in 22% of patients (Kawabe et al., 2006). Adverse events associated with lowering of blood pressure were low.

Thus, agents with α-AR–blocking properties at various levels of neural organization have been used in patients with very varied types of voiding dysfunction—functional outlet obstruction, urinary retention, decreased compliance, and DO. Our own experience would suggest that a trial of such an agent is certainly worthwhile, because the effect or lack of effect will become obvious in a matter of days, and any pharmacologic side effects are, of course, reversible. However, our results with such therapy for non–BPH-related voiding dysfunction have been somewhat less spectacular than those of at least some other investigators.

Nitric Oxide.

In the future, there may be other pharmacologic mechanisms that are explored to produce relaxation in the smooth muscle of the bladder neck, urethra, or prostatic stroma. **Nitric oxide** is a **neurotransmitter capable of producing smooth muscle relaxation, at least in the female rabbit urethra, pig urethra, and human bladder neck** (Andersson and Persson, 1993; Andersson and Wein, 2004). A selective nitrergic action on bladder neck and urethral smooth muscle is an interesting theoretic possibility. Mumtaz et al. (2000) suggested that a topical intraurethral NO donor could induce urethral smooth muscle relaxation without affecting bladder smooth muscle function and that this is a possible clinical avenue of exploration. Mamas et al. (2001, 2003) hypothesized that augmentation of external sphincter NO could be an effective pharmacologic treatment for DSD. In a functional urodynamic study, Reitz et al. (2004a) assessed the effect of the NO donor isosorbide dinitrate on the external urethral sphincter. Magnetic stimulation of the sacral roots was performed in eight healthy men to evoke reproducible contractions of the external urethral sphincter. Sublingual administration of isosorbide dinitrate (10 mg) could significantly reduce the resting pressure of the external urethral sphincter for at least 1 hour. The maximal contractile strength measured as the MUCP during single-pulse and continuous magnetic stimulation of the sacral roots also decreased significantly. NO did not induce a significantly faster fatigue of the external urethral sphincter during continuous magnetic stimulation of the sacral roots. The authors suggested that NO donors could offer a new pharmacologic approach to treat urinary retention caused by an overactive or nonrelaxing external urethral sphincter. In a later study on 12 male SCI patients with NDO and DSD, Reitz et al. (2004b) found that NO significantly reduced external urethral sphincter pressures at rest ($P < .05$) and during dyssynergic contraction ($P < .05$), whereas bladder pressures at rest and during contraction and the reflex volume remained unchanged. In patients who used suprapubic tapping for bladder emptying, the mean post-triggering residual volume was significantly reduced ($P < .05$). The researchers concluded based on their findings that NO donors could offer a potential pharmacologic option to treat DSD in SCI

patients.

At the Level of the Striated Sphincter

There is no class of pharmacologic agents that will selectively relax the striated musculature of the pelvic floor. Three different types of drugs have been used to treat voiding dysfunction secondary to outlet obstruction at the level of the striated sphincter: the benzodiazepines, dantrolene, and baclofen.

The benzodiazepines are classified both as antianxiety agents (Baldessarini, 2006) and as sedative-hypnotics, muscle relaxants, and anticonvulsants (Charney et al., 2006). Dantrolene and baclofen are characterized as antispasticity agents (Standaert and Young, 2006; Taylor, 2006). Baclofen and diazepam exert their actions predominantly within the CNS, whereas dantrolene acts directly on skeletal muscle. Unfortunately, **there is no completely satisfactory form of therapy for alleviation of skeletal muscle spasticity.** Although these drugs are capable of providing variable relief in given circumstances, their efficacy is far from complete; and troublesome muscle weakness, adverse effects on gait, and a variety of other side effects minimize their overall usefulness as treatments for spasticity (Standaert and Young, 2006; Taylor, 2006).

GABA and glycine have been identified as major inhibitory transmitters in the CNS (Andersson and Wein, 2004; Bloom, 2006). GABA is the most widely distributed inhibitory neurotransmitter in the mammalian CNS. GABA receptors have been divided into three types. The GABA-A receptor directly gates a chloride ionophore and has modulatory binding sites for benzodiazepines, barbiturates, neurosteroids, and ethanol (Bloom, 2006). The GABA-B or metabotropic receptor couples to calcium and potassium channels by means of G proteins and second-messenger systems. It inhibits adenylyl cyclase, activates potassium channels, and reduces calcium conductance. The GABA-B receptor is activated by baclofen and is resistant to drugs that modulate GABA-A receptors. There is a third class of GABA receptors, the GABA-C receptor, which is less widely distributed than the A and B subtypes (Bloom, 2006). GABA appears to mediate the inhibitory actions of local interneurons in the brain and presynaptic inhibition within the spinal cord (Bloom, 2006). Glycine receptors are prominent in the brainstem and spinal cord and have many features analogous to the GABA-A receptor.

Benzodiazepines.

Benzodiazepines potentiate the action of GABA by promoting GABA

binding to the GABA-A receptor (Baldessarini, 2006; Charney et al., 2006). Benzodiazepines are extensively used for the treatment of anxiety and related disorders (Baldessarini, 2006), although pharmacologically they can also be classified as centrally acting muscle relaxants. The generalized anxiety disorder that is responsive to pharmacotherapy with these agents is characterized by unrealistic and/or excessive anxiety and worry about life circumstances (Shader and Greenblatt, 1993). Specific symptoms can be related to motor tension, autonomic hyperactivity (frequent urination can be a manifestation of this, and nausea, vomiting, diarrhea, and abdominal distress), and excessive vigilance. Other common uses have included treatment of insomnia, stress-related disorders, muscle spasm, and epilepsy and as preoperative sedation (Lader, 1987). Side effects include nonspecific CNS depression manifesting as sedation, lethargy, drowsiness, a feeling of slowing of thought processes, ataxia, and decreased ability to acquire or store information (Baldessarini, 2006; Shader and Greenblatt, 1993). Some believe that any muscle relaxation effect in clinically used doses is caused by the CNS depressant effects and cite a lack of clinical studies showing any advantages of these agents over placebo or aspirin in this regard (Baldessarini, 2006; Charney et al., 2006). Effective total daily doses of diazepam, the most widely used agent of this group, range from 4 to 40 mg. Other benzodiazepine anxiolytic agents include chlordiazepoxide, clorazepate, prazepam, halazepam, clonazepam, lorazepam, oxazepam, and alprazolam.

Few references are available that provide evaluable data on the use of any of the benzodiazepines in the treatment of functional obstruction at the level of the striated sphincter. Opinions, however, are commonly expressed, at least with regard to diazepam. We have not found the recommended oral doses of diazepam to be effective in controlling the classic type of DSD secondary to neurologic disease. If the cause of incomplete emptying in a neurologically normal patient is obscure and the patient has what appears to be inadequate relaxation of the pelvic floor striated musculature urodynamically (e.g., dysfunctional voiding, occult neuropathic bladder, Hinman syndrome), a trial of such an agent may be worthwhile. The rationale for use is either that of relaxation of the pelvic floor striated musculature during bladder contraction or that such relaxation removes an inhibitory stimulus to reflex bladder activity. Improvement under such circumstances may simply be caused, however, by the antianxiety effect of the drug, or by the intensive explanation, encouragement, and modified biofeedback therapy that usually accompanies such treatment in these patients.

Baclofen.

Baclofen depresses monosynaptic and polysynaptic excitation of motor neurons and interneurons in the spinal cord by activating GABA-B receptors (Standaert and Young, 2006). Baclofen's primary site of action is in the spinal cord, but it is also reported to have activity at more rostral sites in the CNS. Baclofen has been found useful in the treatment of skeletal spasticity from a variety of causes, especially amyotrophic lateral sclerosis (Standaert and Young, 2006). Determination of the optimal dose in an individual patient requires careful titration. Treatment is started at an initial dose of 5 mg twice daily, and the dose is increased every 3 days up to a maximum daily dose of 20 mg four times a day. With reference to voiding dysfunction, Hachen and Krucker (1977) found a daily oral dose of 75 mg ineffective in patients with DSD from traumatic paraplegia, whereas they found a daily intravenous dose of 20 mg highly effective. Florante et al. (1980) reported that 73% of their patients with voiding dysfunction secondary to acute and chronic SCI showed lower striated sphincter responses and decreased residual urine volumes after baclofen treatment, but only with an average daily oral dose of 120 mg. Potential side effects of baclofen include drowsiness, insomnia, rash, pruritus, dizziness, and weakness. It may impair ability to walk or stand and is not recommended for the management of spasticity caused by cerebral lesions or disease. Sudden withdrawal has been shown to provoke hallucinations, anxiety, and tachycardia; hallucinations during treatment, which have been responsive to reductions in dosage, have also been reported (Roy and Wakefield, 1986).

Drug delivery often frustrates adequate pharmacologic treatment, and baclofen is a good example of this. GABA's hydrophilic properties prevent its crossing the blood-brain barrier in sufficient amounts to make it therapeutically useful. For oral use, the more lipophilic analogue, baclofen, was developed. However, its passage through the barrier is likewise limited, and it has proved to be a generally insufficient drug when given orally to treat severe somatic spasticity and micturition disorders secondary to neurogenic dysfunction (Kums and Delhaas, 1991).

Intrathecal infusion bypasses the blood-brain barrier; CSF levels 10 times higher than those reached with oral administration are achieved with infusion amounts 100 times less than those taken orally (Penn et al., 1989). Direct administration into the subarachnoid space by an implanted infusion pump showed initially promising results for not only skeletal spasticity but also striated sphincter dyssynergia and DO.

Nanninga et al. (1989) reported on such administration to seven patients with intractable spasticity. All patients experienced a general decrease in spasticity, and the amount of striated sphincter activity during bladder contraction decreased; six showed an increase in bladder capacity. Four previously incontinent patients were able to stay dry with CIC. The action on DO is not unexpected, given its spinal cord mechanism of action, and this inhibition of bladder contractility when the drug is administered intrathecally may in fact prove to be its most important benefit. Laubser et al. (1991) studied nine SCI patients with refractory spasticity, using an external pump to initially test response. Eight showed objective improvement in functional abilities; three of seven studied urodynamically showed an increase in bladder capacity. Kums and Delhaas (1991) reported on nine paraplegic or quadriplegic men (secondary to trauma or MS) with intractable muscle spasticity treated with intrathecal baclofen. After a successful test period through an external catheter, a drug delivery system was implanted and connected to a spinal catheter. Doses per 24 hours ranged from 74 to 840 µg. Patients were studied before and 4 to 6 weeks after initiation of therapy. Mean residual urine volume decreased from 224 to 110 mL ($P = .01$), mean urodynamic bladder capacity increased from 162 to 263 mL ($P = .005$), and pelvic floor spasm decreased at both baseline and at maximum bladder capacity ($P = .005$ and $P = .025$, respectively). Three subjects became continent. In addition, CIC was no longer complicated by adductor spasm. Bushman et al. (1993) reported an increase in bladder storage in three individuals with hereditary spastic paraplegia treated with intrathecal baclofen. Tolerance to intrathecal baclofen with a requirement for increasing doses may prove to be a problem with long-term chronic use, and studies are underway to investigate this. Vaidyanathan et al. (2004) reported a case with insidious development of autonomic dysreflexia and hydronephrosis resulting from dyssynergic voiding after discontinuation of intrathecal baclofen therapy. They recommended that in SCI patients in whom intrathecal baclofen therapy is terminated, close monitoring of the urologic status is needed.

Dantrolene.

Dantrolene exerts its effects by a direct peripheral action on skeletal muscle (Standaert and Young, 2006; Taylor, 2006)**. It is thought to inhibit the excitation-induced release of calcium ions from the sarcoplasmic reticulum of striated muscle fibers, thereby inhibiting excitation-contraction coupling and diminishing the mechanical force of contraction.** The blockade of calcium release is not complete, however, and contraction is not completely abolished. It reduces reflex more than voluntary contraction, probably because of a preferential action on fast-type, as compared with slow-type, skeletal muscle fibers. It has been shown to have therapeutic benefits for chronic spasticity associated with CNS disorders.

The drug has been reported to improve voiding function in some patients with classic DSD and was initially reported as being very successful in doing so (Murdock et al., 1976). Therapy in adults is recommended to begin at a dose of 25 mg daily, and this is gradually increased by increments of 25 mg every 4 to 7 days to a maximal oral dose of 400 mg given in four divided doses. Hackler et al. (1980) achieved improvement in voiding function in approximately one-half of their patients treated with dantrolene but found that such improvement required oral doses of 600 mg daily. Although no inhibitory effect on bladder smooth muscle seems to occur (Harris and Benson, 1980), the generalized weakness that dantrolene can induce is often significant enough to compromise its therapeutic effects. Other potential side effects include euphoria, dizziness, diarrhea, and hepatotoxicity. Fatal hepatitis has been reported in 0.1% to 0.2% of patients treated with the drug for 60 days or longer, and symptomatic hepatitis may occur in 0.5% of patients on treatment for more than 60 days, whereas chemical abnormalities of liver function are noted in up to 1%. The risk for hepatic injury is twofold greater in female patients (Ward et al., 1986).

One agreed-on use of dantrolene is to acutely manage malignant hyperthermia, a rare hereditary syndrome characterized by vigorous contraction of skeletal muscle precipitated by excess release of calcium from the sarcoplasmic reticulum, usually in response to neuromuscular-blocking agents or inhalational anesthetics. Almost all hospital pharmacies stock parenteral dantrolene for this purpose. **Virtually no one currently uses dantrolene for the treatment of voiding dysfunction.**

Botulinum Toxin.

As mentioned earlier, botulinum toxin is an inhibitor of the release of ACh and other transmitters at the neuromuscular junction of somatic nerves in striated muscle, and of autonomic nerves in smooth muscle (Simpson, 2004). It is interesting that it produces enough weakness of the muscle to prevent or considerably ameliorate spasm or involuntary contraction but not to completely block voluntary control, a phenomenon hypothesized to occur because more active neuromuscular junctions are more likely than less active junctions to be blocked by the effect of the drug (Hallett, 1999). **Dykstra et al. first reported its urologic use for the treatment of DSD** (Dykstra and Sidi, 1990; Dykstra et al., 1998, 2003). Injections were carried out weekly for 3 weeks, achieving a duration of effect averaging 2 months. The only side effects reported in the Dykstra articles were transitory limb paresis and transitory exacerbation of autonomic hyperreflexia.

Fowler et al. (1992a) injected botulinum toxin to six women with difficult voiding and urinary retention secondary to what is now called *Fowler syndrome* (manifesting with abnormal myotonus-like electromyographic activity in the striated urethral sphincter). Although voiding characteristics improved in no patient (a fact attributed to the type of repetitive discharge activity), three women did develop transient stress incontinence, a positive effect of sorts, indicating that the sphincter muscle had indeed been weakened. Petit et al. (1998) reported on the endoscopic injection of botulinum toxin A (Botox), 150 IU, into the striated urethral sphincter, using a four-point injection technique (medication was diluted to 4 mL with saline solution). Seventeen patients with SCI or spinal cord disease were treated, and evaluation 1 month after treatment disclosed the following positive results: (1) a decrease in PVR by an average of 176 mL; (2) a decrease in bladder pressure during an emptying contraction by an average of 19 cm H_2O; and (3) a decrease in urethral pressure during an emptying bladder contraction by an average of 24 cm H_2O. The authors judged voiding to be improved in 10 patients. Side effects included the new appearance of stress incontinence in two patients and exacerbation of preexisting incontinence in three. The duration of the effect was variable, but no less than 2 to 3 months. There were no adverse effects on striated muscle elsewhere. The authors concluded that Botox was a promising treatment for DSD in certain patients who are refractory to CIC or surgery. Gallien et al. (1998) injected Botox transperineally in five men with traumatic quadriplegia and DSD. Using a total initial dose of 100 units, divided into four injections of 25 U each, the authors noted what they called improved bladder function in all patients, with a significant decrease in residual urine volume (however, on examination of the figures, the mean reduction was only 14 mL, with one patient requiring a second set of injections). The maximum urethral pressure on average did not change, the maximum detrusor pressure during an emptying episode decreased 5 cm H_2O, and the functional detrusor capacity increased by an average of 89 mL. Urinary catheterization was able to be stopped in two patients, and autonomic hyperreflexia dramatically decreased in intensity in four patients. The time to improvement was 10 to 21 days, and the duration was 3 to 5 months. No patient had significant side effects. Wheeler et al. (1998) reported on three men with SCI, all of whom had emptying problems related to DSD. The sphincter was injected transperineally with botulinum toxin, using electromyographic control for localization. Two of the patients reported excellent results. Schurch et al. (1996) used both transurethral and transperineal injections in 24 male SCI patients with voiding dysfunction secondary to DSD. They judged that in 21 of these patients, DSD was significantly improved, with a concomitant decrease in PVR urine volume in “most cases.” Nine of 24 patients had a decreased PVR volume from 450 to 50 mL; in 7 patients, the residual urine volumes were less than 50 mL to begin with and remained unchanged; and in 8 patients, the PVR urine volumes were high and remained unchanged. The authors commented that transurethral injections appeared to be more effective, at least in reduction in maximum urethral pressure, than did transperineal injections. They noted no side effects. de Sèze et al. (2002) performed a double-blind lidocaine-controlled study in 13 patients with spinal cord disease and DSD and demonstrated the superiority of botulinum toxin compared with lidocaine in improving clinical symptoms and increased urethral pressure.

A potential side effect is the spread to nearby muscles, particularly when high volumes of the toxin are injected. Distant effects can also occur, but distant weakness or generalized weakness, caused by the toxins spreading in the blood, is very rare. Botulinum toxin should be used only under close supervision in patients with already disturbed neuromuscular transmission or during treatment with aminoglycosides.

Theoretically, any agent that promotes striated sphincter relaxation in a uroselective manner could be used to decrease outlet resistance and facilitate voiding dysfunction. Yoshiyama et al. (2000) described the laboratory use of intravenous α-bungarotoxin as improving voiding in SCI rats. The drug is a toxin extracted from the venom of a Formosan snake; it selectively blocks nicotinic receptors without influencing transmission in autonomic ganglia. Although a long way from clinical use, nicotinic receptors in the striated sphincter have been shown to be a potential target for drug therapy for DSD.

Key Points: Decreasing Outlet Resistance

- α-AR–blocking agents are capable of reducing smooth muscle tone in the bladder outlet in both men and women and in the prostatic muscle. Such agents can be used with success in patients with bladder neck dysfunction and in men with BOO secondary to prostatic enlargement. Blockade of the α_{1A}-AR would theoretically exert the greatest effect, and whether there is any difference in the efficacy of the individual agents available remains a topic of controversy.

- There is no class of pharmacologic agents that will selectively relax the striated musculature of the pelvic floor. There are few references that provide any information regarding efficacy of benzodiazepines for this purpose. Baclofen seems to be most useful when administered intrathecally; dantrolene is seldom if ever used for this purpose. Injection of botulinum toxin into the striated sphincter has been used with some clinical success, especially in patients with neurologic DSD. The potential for spread to nearby structures is greater than with intravesical therapy, and distant effects can also occur, but these are rare.

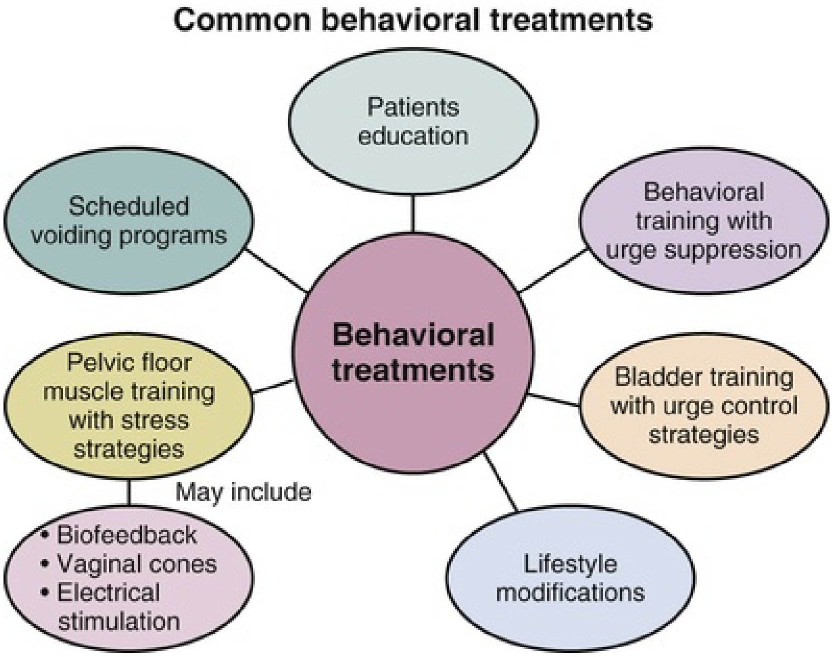
Conservative Management of Urinary Incontinence

Behavioral and Pelvic Floor Therapy, Urethral and Pelvic Devices

Diane K. Newman DNP, ANP-BC, FAAN, Kathryn L. Burgio PhD

Conservative behavioral treatments for urinary incontinence (UI) and associated lower urinary tract symptoms (LUTS) include any therapy not involving surgical treatment (Moore et al., 2013). Because behavioral treatments are effective and essentially risk free, they are the mainstay of conservative treatment and are recommended as first-line therapy by several guidelines and consensus panels (Dumoulin et al., 2017; Gormley et al., 2015; Hartmann et al., 2009; Shamliyan et al., 2008). **Behavioral treatments are a group of interventions that improve UI and LUTS by changing patients' behavior or environment or by teaching new skills.**

Behavioral treatment programs usually comprise multiple components; the best programs are individualized according to the patient's condition, needs, and environment. **Components of a behavioral program may include patient education and any of the following: self-monitoring (bladder diary), pelvic floor muscle training (PFMT) and pelvic floor muscle exercise (PFME), active use of pelvic floor muscles (PFMs) for urethral occlusion ("stress strategies," the "knack"), urge prevention and suppression techniques (urge strategies), bladder training (BT) with urge control techniques (distraction, self-assertions), biofeedback (BF), electrical stimulation (E-stim), fixed or incremental voiding schedules, delayed voiding, fluid management, caffeine reduction, dietary changes, weight loss, teaching normal voiding techniques, and/or other lifestyle changes.** The most common behavioral interventions are depicted in Fig. 121.1, and a list of LUTS to which they are potentially applicable is presented in eTable 121.1. In most urologic settings, conservative treatment programs are designed and administered by advanced practice providers (APPs) (Newman, 2014; Newman and Wein, 2013) after a simple, noninvasive assessment.



Common behavioral treatments
Patients education
Scheduled voiding programs
Behavioral training with urge suppression
Behavioral treatments
Pelvic floor muscle training with stress strategies
Bladder training with urge control strategies
May include
• Biofeedback
• Vaginal cones
• Electrical stimulation
Lifestyle modifications

FIG. 121.1 Common behavioral treatments.

eTABLE 121.1

Conditions for Which Behavioral Treatments Have Shown Benefit

Stress urinary incontinence
Overactive bladder (urgency, frequency)
Urgency urinary incontinence
Neurogenic detrusor overactivity
Mixed urinary incontinence
Nocturia
Pelvic floor muscle spasm (dysfunction, high tone muscle)
Nonrelaxing striated sphincter

Modified from Newman DK, Wein AJ: *Managing and treating urinary incontinence*, ed 2, Baltimore, 2009, Health Professions Press, pp 245–306; Newman DK, Wein AJ: Office-based behavioral therapy for management of incontinence and other pelvic disorders. *Urol Clin North Am* 40(4):613–635, 2013.

The most established behavioral treatment programs are PFMT, behavioral training with urge suppression, and BT. These therapies encompass **two fundamental approaches** to treating LUTS. One approach focuses on the **bladder *outlet***, teaching skills for improving pelvic floor muscle (PFM) strength and control and techniques for suppressing bladder urgency. The other approach focuses on **controlling bladder *function* by changing voiding habits,** such as with BT and delayed voiding, also supported with urge control techniques. These therapies are grounded in the concept that patients with LUTS can be educated about their condition and develop skills and strategies to reduce or eliminate symptoms.

Behavioral treatments can also be categorized as **"patient dependent"** or **"caregiver dependent"** (Newman et al., 2014, 2018). BT, PFMT, and behavioral training are examples of "patient-dependent" interventions because they rely on active patient participation. These therapies require adequate function, learning capability, and motivation of the individual. **Caregiver-dependent interventions, such as prompted voiding (PV), are useful in people with functional disabilities.** The success of these interventions is largely dependent on caregiver knowledge and motivation, rather than on the patient's physical function and mental status.

In addition to these established primary treatment approaches that focus on improving the patient's direct control over bladder and PFM function, **a number of lifestyle modifications may improve LUTS indirectly by changing the patient's behavior or avoiding factors that exacerbate symptoms or make the bladder more difficult to control.** These interventions include fluid management, caffeine reduction, reduction of bladder irritants, management of constipation, smoking cessation, and weight loss.

Behavioral (conservative) treatments are supported by a large body of research (Dumoulin et al., 2017) and have been recommended as treatment for UI and non-neurogenic overactive bladder (OAB) by multiple organizations (Gormley et al., 2015; Qaseem et al., 2014; Shamliyan et al., 2008) and international guidelines (Dumoulin et al., 2017). The International Consultation on Incontinence (ICI) Committee on Adult Conservative Management (Dumoulin et al., 2017) details evidence and recommendations for all conservative behavioral treatments for women, men, and frail older adults (eBoxes 121.1, 121.2, and 121.3) using the Oxford grading system (eBox 121.4). In this chapter, we also describe a number of devices that can prevent urine loss mechanically.

eBox 121.1

Lifestyle Modifications: International Consultation on Incontinence Recommendations

Obesity (Weight Loss)

Weight loss of 5% of initial body weight has an impact on the reduction of UI symptoms, and the odds of developing UI at 1 year can be reduced by 3% for every kilogram lost by overweight and obese women. Weight loss as a nonsurgical intervention should be considered a first-line treatment to reduce UI in obese and overweight women.

Grade of Recommendation: A

Weight loss through lifestyle changes should be recommended to obese and overweight men with UI, particularly those with type 2 diabetes.

Grade of Recommendation: B

Physical Activity

Moderate exercise may help in decreasing the incidence of UI; this effect may be mediated by weight control.

Grade of Recommendation: C

Constipation-Chronic Straining

There is some evidence to suggest that chronic straining during defecation may be a risk factor for the development of UI.

Dietary Modification

Indications from epidemiologic data suggest diet may play a role in UI. Minor decrease of fluid intake by 25% may be recommended provided baseline consumption is not less than 30 mL/kg a day.

Caffeine reduction may help in improving incontinence and related symptoms.

Grade of Recommendation: B

A reduction in caffeine intake is recommended for those with incontinence symptoms; evidence suggests the equivalent of 2 cups of coffee a day (250 mg) is associated with UI in men and women.

Grade of Recommendation: C

Smoking

Data suggest that smoking increases the risk of more severe UI and that urinary frequency may be improved by smoking abstinence. There remains a need for further prospective studies of smoking cessation for urinary symptoms.

Grade of Recommendation: B

Smoking abstinence should be recommended for men with UI.

Grade of Recommendation: C

Modified from Dumoulin C, Adewuyi T, Booth J, et al.: Adult conservative management. In Abrams P, Cardozo L, Wagg A, Wein A, editors: *Incontinence, 6th International Consultation on Incontinence*, International Continence Society, Bristol, UK, 2017, pp 1443–1628.

eBox 121.2

International Consultation on Incontinence Levels of Evidence for Frail Older Adults

RECOMMENDATIONS FOR PRACTICE	LEVEL OF EVIDENCE

Late afternoon administration of a diuretic may reduce nocturia in persons with lower extremity venous insufficiency or congestive heart failure unresponsive to other interventions.	2
Prompted voiding is effective in the short-term treatment of daytime UI in nursing home residents and home-care clients when caregivers comply with the protocol.	1
Prompted voiding is ineffective and should not be used for people who need the assistance of more than one person to transfer, cannot follow a one-step command, have less than a 20% reduction in wet checks or less than a 66% appropriate toileting rate after a 3-day trial; these people should be managed with “check and change.”	1
Interventions combining toileting and functional training decrease urine loss and improve endurance in nursing home residents.	1
It is uncertain whether habit retraining or timed voiding reduces UI in frail older persons.	4
It is uncertain whether bladder training reduces UI in frail older persons.	4
Biofeedback-assisted PFMT in combination with bladder training reduces UI in homebound older adults.	2
Functional training in combination with PFMT reduces UI and improves walking time in frail older women.	2
There are no proven interventions to reduce the incidence of UI in hospitalized frail older persons.	4

PFMT, Pelvic floor muscle training; *UI,* urinary incontinence.

Modified from Wagg A, Chen LK, Johnson T, et al.: Incontinence in frail older persons. In Abrams P, Cardozo L, Wein A, et al., editors: *Incontinence. Proceedings from the 6th International Consultation on Incontinence,* Bristol, UK, 2017, International Continence Society, pp 1309–1442.

eBox 121.3

International Consultation on Incontinence Recommendations for Conservative Behavioral Treatments

GROUP	RECOMMENDATION	GRADE
PELVIC FLOOR MUSCLE TRAINING		
General	Clinicians should provide the most intensive health professional-led PFMT program possible	A

	within service constraints because programs that are taught and supervised by health professionals are better than those with little or no supervision.	
	Although studies are limited, there does not appear to be clear benefit for adding other modalities (i.e., motor learning, abdominal- or hip-muscle training, intravaginal resistance device) to PFMT.	B
	There is no clear benefit from adding clinic or home-based BF to a PFMT program. The use of clinic or home-based BF should remain a therapist/individual decision based on individual's needs and service constraints.	B (clinic/office based) B (home based)
	There is evidence of benefit that PFMT is effective in reducing pelvic floor symptoms.	A
Women with UI	Supervised PFMT should be offered as first-line conservative therapy to women with UI.	A
Older women	There is preliminary evidence that PFMT may help prevent UI.	C
Prevention of UI in childbearing women	Continent, pregnant women should be offered a supervised (including regular health professional contact) and intensive strengthening antepartum PFMT program to prevent antepartum and postpartum UI.	A
Treatment of UI in childbearing women	PFMT should be offered as first-line conservative therapy to women with persistent UI symptoms 3 months after delivery.	**A**
	An “intensive” PFMT program (in terms of supervision and exercise content) is likely to increase the treatment effect.	B
Prevention/treatment of UI in childbearing women	Health providers should carefully consider the cost/benefit of population based approaches to health professional taught antepartum or postpartum PFMT, that is, health professional instruction to all pregnant or postpartum women regardless of their current or prior continence status.	A (antepartum) B (Postpartum)
	Where a population approach is used, the “best” evidence suggests the following: (a) an intervention comprising a daily home PFMT and weekly physiotherapist-led exercise classes	C

	for 12 weeks, starting at 16–24 weeks' gestation for pregnant women, and (b) an individually taught strengthening PFMT program that incorporates adherence strategies for postpartum women who have had a forceps delivery or a vaginal delivery of a large baby (4000 g or more).	
Women with stress UI	PFMT and VC are both effective as conservative therapy, although PFMT is superior.	B
	PFMT is better than E-stim as first-line conservative therapy.	B
	PFMT is better than BT as first-line conservative therapy.	B
	PFMT and drug therapy are effective as first-line treatment; PFMT avoids the adverse effects experienced with drug therapy.	B
	Surgery is more effective than PFMT, but potential benefit should be weighed against potential adverse events. PFMT should be offered as first-line conservative therapy.	B
	PFMT and continence pessary are both effective as first-line conservative therapy.	
	In treatment of women with stress UI and vaginal atrophy, combining PFMT and intravaginal estrogen may be better than estrogen alone.	C
Women with stress UI or mixed UI	VC does not appear to be better than PFMT in the treatment of UI. PFMT should be recommended as first-line conservative therapy.	B
	VCs with supervised training sessions by a trained health professional can be offered to women who can and are prepared to use them. VC may be inappropriate for some women because of inability to insert or retain the cone or because of side effects and discomfort.	B
Women with urgency UI	PFMT and BT should be offered as effective first-line conservative therapy.	B
	For treatment of urgency UI (tolterodine) but not for stress UI (duloxetine), consider adding PFMT to drug therapy.	B

Women with urgency UI or mixed UI	PFMT and BT should be offered as effective first-line conservative therapies.	B
	PFMT is better than oxybutynin as first-line therapy.	B
Women with stress UI, urgency UI or mixed UI	Consider a combination of PFMT and BT rather than BT alone.	C
Women with POP	PFMT does not influence the development of prolapse postnatally.	B
	PFMT intervention delivered 12 years+ after childbirth can reduce symptoms of prolapse, which develop in the longer term.	B
	There is some evidence of benefit showing that PFMT is effective in alleviating specific prolapse symptoms (e.g., vaginal bulge).	C
	There is no evidence that PFMT is effective in reducing severity of prolapse based on POP-Q stage.	B
	Perioperative PFMT does not improve prolapse symptoms in women undergoing surgery for vault prolapse.	B
	Combined pessary and PFMT and PFMT alone can be equally effective in reducing symptoms and increasing muscle strength and should be considered for treatment.	B
Men post-prostatectomy	Some preoperative or immediate postoperative instruction in PFMT for men undergoing radical prostatectomy may be helpful in earlier recovery of continence.	B
	The use of BF to assist PFMT is currently a therapist/patient decision based on economics and preference. The use of BF in clinic/office setting, over and above home PFMT, should remain a therapist/individual decision based on economics and preference.	B
	It is not clear whether PFMT taught by digital rectal examination (DRE) offers any benefit over and above verbal or written instruction in PFMT.	B

	There does not appear to be any benefit of adding E-stim to a PFMT program for men with persistent post-prostatectomy UI.	B
Men with symptoms of postmicturition dribbling	Offer men with PMD instruction to do a strong PFM contraction immediately after voiding or urethral massage to empty the urethra.	C
VAGINAL CONES		
General	VCs may be inappropriate in some cases because of inability to insert or retain the cone or because of side effects and discomfort. Trained health professional assessment is recommended.	D
Women with stress UI	VC with supervised training sessions by a trained health professional may be offered as a first-line conservative therapy to those who can and are prepared to use them.	B
Women with stress UI or mixed UI	VCs do not appear to be better than PFMT in the treatment of UI.	B
PELVIC FLOOR ELECTRICAL STIMULATION (E-STIM)		
General	Based on current limited evidence, E-stim could be considered as an alternative to medical treatment.	B
	The addition of E-stim to PFMT or BF-assisted PFMT program does not appear to add benefit.	B
Women with stress UI	E-stim may be better than no treatment to improve symptoms and QoL.	B
	Maximal clinic-based E-stim may be better than daily low-intensity home-based E-stim in improving symptoms.	B
Urgency UI	May be considered for treatment to improve symptoms	B
BLADDER TRAINING		
General	Clinicians should provide the most intensive BT supervision possible within service constraints.	D
	Clinicians and researchers are advised to refer to the operant conditioning and educational literature to provide a rationale for their choice of training parameters or approach.	D
	Timed voiding with a 2-hour voiding interval may be considered as a sole intervention for women with mild UI or	C

	infrequent voiding patterns. Timed voiding may also be considered as an adjunct to other treatment. A 2-hour timed voiding interval may be beneficial in treating women with mild UI or infrequent voiding patterns.	
	Routine addition of a “simplified” BT to drug therapy does not provide additional improvement in urgency but should be considered in treatment of voiding frequency in women with UI and OAB.	B
	BT should be offered as treatment for urinary frequency and nocturia, but in choosing between BT and an anticholinergic drug for women with frequency, either may be effective.	B
Women with UI	BT should be recommended as first-line conservative therapy.	A
Women with UI and/or OAB	Insufficient evidence exists to support the use of BT to treat urgency in women with UI and/or OAB or to guide the choice of BT vs. drug treatment as initial treatment aimed at urinary urgency.	D
In combination with drug therapy	When considering BT and anticholinergic drug in women with DO or UUI, either may be effective.	B
	BT may be preferred by women and clinicians because it is not associated with the drug-related side effects.	D
	Limited evidence suggests the addition of written information on BT for women with OAB and on an antimuscarinic drug does not further improve UI.	B
	Routine addition of a “simplified” BT to drug therapy does not provide additional improvement in urgency but should be considered in treatment of voiding frequency in women with UI and OAB.	B
In combination with PFMT	The available evidence (single trial) supports the use of BT as a supplement to PFMT in improving short-term outcomes but not longer-term results.	C

BF, Biofeedback; *BT,* bladder training; *DO,* detrusor overactivity; *E-stim,* electrical stimulation; *OAB,* overactive bladder; *PFMT,* pelvic floor muscle training; *POP-Q,* pelvic organ prolapse-quantification; *QoL,* quality of life; *UI,* urinary incontinence; *UUI,* urgency urinary incontinence; *VC,* vaginal cone.

eBox 121.4

Oxford Levels of Evidence and Grades of Recommendation

LEVEL	EVIDENCE
1	Usually involves meta-analysis of randomized controlled trials (RCTs) or a good quality RCT, or "all-or-none" studies in which no treatment is not an option, for example, in vesicovaginal fistula.
2	Includes "low"-quality RCT (e.g., <80% follow-up) or meta-analysis (with homogeneity) of good-quality prospective "cohort studies." These may include a single group when individuals who develop the condition are compared with others from within the original cohort group. There can be parallel cohorts in which those with the condition in the first group are compared with those in the second group.
3	Includes: • Good-quality retrospective "case-control studies" in which a group of patients who have a condition are matched appropriately (e.g., for age, sex) with control individuals who do not have the condition. • Good-quality "case series" in which complete group of patients, all with the same condition/disease/therapeutic intervention, are described, without a comparison control group.
4	Includes expert opinion in which the opinion is based not on evidence, but on "first principles" (e.g., physiologic or anatomic) or bench research. The Delphi process can be used to give "expert opinion" greater authority. In the Delphi process a series of questions are posed to a panel; the answers are collected into a series of "options"; the options are serially ranked; if a 75% agreement is reached, then a Delphi consensus statement can be made.

Uses four grades from the Oxford system. As with the levels of evidence, the grades of evidence may apply either positively (do the procedure) or negatively (do not do the procedure).

GRADE	RECOMMENDATION
A	Usually depends on consistent level 1 evidence and often means that the recommendation is effectively mandatory and placed within a clinical care

	pathway. However, there will be occasions where excellent evidence (level 1) does not lead to a grade A recommendation, for example, if therapy is prohibitively expensive, dangerous, or unethical. Grade A recommendation can follow from level 2 evidence. However, a grade A recommendation requires a greater body of evidence if based on anything except level 1 evidence.
B	Usually depends on consistent level 2 and/or 3 studies or "majority evidence" from RCTs.
C	Usually depends on level 4 studies or "majority evidence" from level 2 and/or 3 studies or Delphi processed expert opinion.
D	"No recommendation possible" would be used when the evidence is inadequate or conflicting and when expert opinion is delivered without a formal analytical process, such as by Delphi.

Any level of evidence may be positive (the therapy works) or negative (the therapy doesn't work). A level of evidence is given to each individual study.

Modified from Abrams P, Khoury S, Grant A: Evidence based medicine—overview of the main steps for developing and grading guideline recommendation. In Abrams P, Cardozo L, Khoury S, et al., editors: *Incontinence*, EAU/ICUD, 2013, pp 8–9, (website): https://www.ics.org/Publications/ICI_5/INCONTINENCE.pdf.

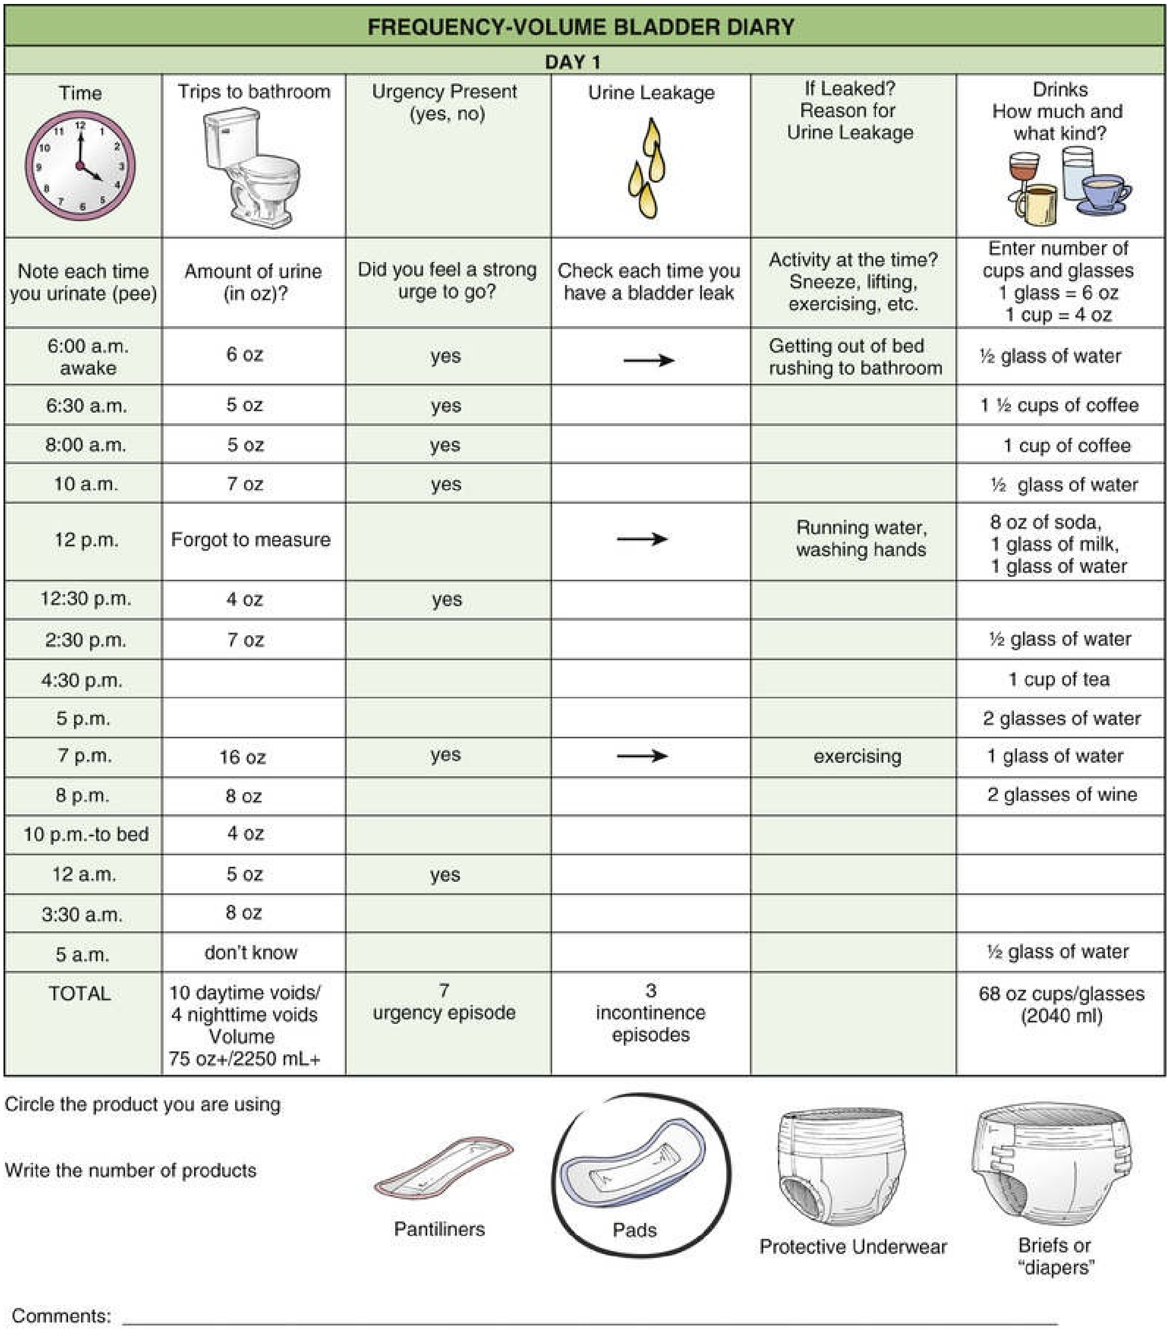
Indications

Behavioral interventions are conservative treatments that are well established for treating stress, urgency, and mixed UI and OAB. Behavioral interventions are also appropriate for voiding dysfunction, although less evidence exists for this condition. Although most patients experience some degree of improvement, there is wide variation in outcomes and little is known of the characteristics of patients who respond best to behavioral treatment. **Therefore, because they are virtually risk free, behavioral treatments should be offered as first-line therapy to any man or woman who is willing and able to participate**. Even patients with dementia can benefit from the appropriate, caregiver-guided behavioral treatment program.

Assessment Before Behavioral Treatments

Perhaps the most important step in evaluating the patient with LUTS is gathering a **focused** and **detailed history,** including onset of symptoms, duration, progression, characteristics, and situational antecedents or “triggers” (Newman, 2005; Newman and Wein, 2013). Understanding these factors will determine the design of a behavioral treatment program and guide its implementation.

To supplement the history, it is very useful for the patient to complete a 3- to 7-day bladder diary or frequency volume chart (Locher et al., 2001; Tincello et al., 2007; Fig. 121.2). **The diary is a valuable tool for the patient as well as for the provider.** In the assessment phase, the diary provides information on the type and amount of fluid intake, type and frequency of symptoms, such as incontinence episodes, frequency (and amount) of urination, the urgency associated with each, and the circumstances or reasons for incontinence episodes, which helps the provider plan appropriate components of behavioral intervention (Sampselle, 2003). Many providers are interested also in having the patient note the type and quantity of absorbent incontinence pads used and to quantify amount of urine leakage.



FREQUENCY-VOLUME BLADDER DIARY

DAY 1

FIG. 121.2 Example of a completed frequency-volume bladder diary.

A bladder diary is also the best noninvasive tool available to objectively monitor the patient's voiding habits and the effect of treatment on symptoms, guiding the use of various treatment components. Voided volumes, included in a frequency-volume record, may be more burdensome for patients to document, but they provide a practical estimate of the patient's functional bladder capacity in daily life.

In addition to guiding behavioral treatment from the provider's perspective, **the self-monitoring effect of completing a diary can enhance patients' awareness of drinking and voiding habits and helps them recognize how their LUTS, especially incontinent episodes, may be related to their activities.** This increased awareness is thought to empower patients to help them retrain more effectively (Vella et al., 2012). A review of a diary can assist patients in identifying the times when they are at increased risk of a UI episode and activities that precipitate UI episodes, which helps them be prepared to implement behavioral skills.

Another approach to collecting information on bladder habits is the validated Questionnaire-Based Voiding Diary (QVD) for self-assessment of the type and volume of fluid intake and the type of UI which can be completed in an initial office visit in 5 to 7 minutes (Arya et al., 2008, 2011; eFig. 121.3).

QUESTIONNAIRE-BASED VOIDING DIARY (QVD)

Patient Education

Because behavioral treatments are based on principles of learning, an important first step in any behavioral program is to provide basic education so that patients can understand their condition, the treatment process, and the therapeutic goals. Patient education includes an explanation of the anatomy of the bladder, urethra, vagina/prostate, PFMs, and rectum; how they function and are interrelated; and the causes and mechanisms of their particular condition. **It is essential for patients to understand that a behavioral program is based on changing habits and learning new skills, and that improvement is often gradual** (Lukacz et al., 2011). Further, understanding that their results will depend on active participation and daily practice facilitates adherence and realistic expectations about therapeutic outcomes.

Pelvic Floor Muscle Training

PFMT and exercise, also known as pelvic floor rehabilitation (Payne, 2012) **is a cornerstone of behavioral treatment for UI and urinary urgency and frequency.** First described by Margaret Morris in 1936, it was originally designed to teach patients how to control and exercise peri-vaginal muscles with the goal of strengthening the muscles and reducing stress UI. PFMT and PFME were first popularized by Arnold Kegel, a gynecologist who proposed that stress UI was due to a lack of awareness of function and coordination of PFMs (Kegel, 1948). Kegel also demonstrated that women could reduce their stress UI through repetitive muscle contractions to increase strength (Kegel, 1948, 1956). Over time, this intervention has evolved as a nurse-directed behavior treatment and as a physical therapy, combining principles from both fields into a widely accepted conservative treatment for incontinence and other LUTS (Newman et al., 2018).

In women, it is postulated that a PFM contraction may raise the urethra and press it toward the symphysis pubis, prevent urethral descent, and improve structural support of the pelvic organs (Berghmans et al., 1998). **PFMT may result in hypertrophy of the striated muscles, thus increasing the external mechanical pressure on the urethra. Intensive PFMT is also hypothesized to reinforce structural support of the bladder neck in women, limiting its downward movement during increases in abdominal pressure** (Bø, 1995, 2004).

PFMT involves the patient learning how to contract and relax the PFM, performing a regular exercise regimen to improve strength and control, and actively using a PFM contraction to occlude the urethra during physical activities that increase abdominal pressure and precipitate urine leakage (Miller et al., 1998). Details of training regimens vary, and few are well described in the current evidence-based literature (Dumoulin et al., 2017; Newman et al., 2018).

Assessment of Pelvic Floor Muscle Function

Before initiation of PFMT, an assessment of the PFM can provide useful baseline information about strength, coordination, and control. **PFM function can be assessed by several methods, including visual observation, digital palpation, electromyography (EMG), manometry, or ultrasound.** In women, visual observation can be used to assess a correct PFM contraction, which is seen by perineal elevation (inward [ventrocephalad] movement of the vulva, perineum, and anus) or an incorrect contraction exhibited by perineal descent (excessive dorsocaudal movement of the vulva, perineum, and anus) (Bø et al., 2017). Digital assessment is the most commonly used technique in clinical practice (Newman and Wein, 2009, 2013; Newman et al., 2018). The most widely used digital palpation methods are the Brink score and the Laycock PERFECT (Power, Endurance, Repetitions, Fast, Every, Contraction, Timed) assessment scheme (Newman and Laycock, 2008). The Brink score employs a 4-point scale to assess the contraction pressure, vertical displacement, and endurance of squeeze (Brink et al., 1989). The Laycock PERFECT assessment scheme uses a 6-point scale to score strength and endurance and the number of repetitions and fast contractions (Laycock and Jerwood, 2001).

PFM strength can be determined in women by inserting one or two fingers into the vagina to the level of the first knuckle, then palpating the muscular attachments along the pubic arch and the insertion of the levator ani and coccygeus muscles (Newman, 2014, Newman and Laycock, 2008). The levator ani can be palpated just superior to the hymeneal ring, at the 4 and 8 o'clock positions, to determine strength, and whether palpation reproduces any discomfort or tenderness. The patient is asked to contract the PFMs around the examiner's finger with as much force and for as long as she is able and in short, fast contractions called “flicks.” Tactile feedback in the form of tapping or a slight, quick muscle stretch can be used to assist the patient in identifying the PFMs. Tactile feedback may enhance verbal feedback and help a patient who may not know what muscle to contract, does not understand how to contract the PFMs, and/or has very weak PFMs. **It is important to realize that, when asked to contract the PFM, women may use the wrong muscles,** straining down or performing a Valsalva maneuver**, or fail to activate all layers of the pelvic musculature.** The examiner notes through observation whether accessory muscles (such as gluteal, abdominal muscles) also contract.

When assessing PFM strength, clinicians should use three criteria (Brink et al., 1989) and note the results:

- Pressure: The amount of pressure or strength of the muscle contraction, which can range from imperceptible to a firm squeeze
- Duration: The number of seconds that the examiner feels the

muscle contraction
- Alteration in position: In a well-supported pelvic floor, the muscle contraction can lift the base of the examiner's finger. Use of accessory muscles should be noted (abdominal movement, gluteal lifting). If the patient has an “overactive PFM” (voluntary PFM relaxation is absent or partial), the degree should be noted. Overactive PFM (also referred to as high tone muscle) is defined as one that does not relax or may even contract when relaxation is functionally needed (e.g., during micturition) (Messelink et al., 2005).

Assessment of the PFM in men and women can also be performed by evaluating anal sphincter contraction and tone. This is done by having the patient relax and bear down. As the sphincter relaxes, the examiner gently inserts an index finger into the anal canal in a direction pointing toward the umbilicus. Normally, the muscles of the anal sphincter close snugly around the entire circumference of the examiner's finger. The puborectalis portion of the levator ani muscle can be palpated about 2.5 to 4 cm from the anal verge. To assess the strength of the sphincter muscle, the patient is asked to tighten the rectum. The examiner should feel a griping or “pulling in” around the entire finger circumference. Resting sphincter tone can be noted as weak, moderate, or strong.

Teaching Pelvic Floor Muscle Control

The first step in PFMT is to teach the patient how to identify the PFMs and to contract and relax them reliably. This can be done using verbal feedback based on vaginal or anal palpation during a digital assessment. It can also be done using visual or auditory BF or E-stim (Newman, 2014; Newman and Wein, 2009, 2013). Instructions to patients can include the following:

- “Contract your muscles around my finger(s). Try to pull up and in.”
- “Without tensing the muscles of your legs, buttocks, or stomach, imagine trying to prevent the passing of gas or pinching off a stool by tightening the ring of muscles around the anus. A closing

and lifting sensation should be felt."

- For men: "Imagine moving the penis up and down without moving any other part of the body."
- For women: "You should feel your vagina and rectum pull up and in."

One problem commonly encountered in teaching PFM control is muscle isolation; more than one-third of women report not feeling confident about their ability to do a PFM contraction correctly (Chiarelli et al., 2003). Patients tend to recruit other muscles (referred to as co-contractions), such as the rectus abdominis muscles or gluteal muscles, instead of or in addition to the PFMs (Newman et al., 2018). Women substitute a straining-down Valsalva maneuver, which threatens to worsen the very condition the contractions are intended to prevent or treat (Sampselle and DeLancey, 1992). Contracting certain abdominal muscles can be counterproductive when it increases pressure on the bladder or pelvic floor. **Thus it is important to observe for the use of other muscles and to help patients to contract PFMs selectively while relaxing ancillary muscles.** Instructing patients not to hold their breath or to count out loud can be helpful to avoid bearing down. Coordinated training of transversus abdominis muscles has also been recommended by some clinicians because it is believed that these muscles facilitate PFM contraction. However, in a review of the literature, Bø et al. (2009) noted an absence of evidence for this type of training, and it remains controversial.

It is important to verify that patients have identified and can contract the PFMs properly before initiating an exercise regimen. Not being able to identify the PFMs or to exercise them correctly may be the most common reason for poor outcomes with this treatment modality. PFM control is a skill that may take time to master, but with repeated training, most patients are successful.

In the past, most patients were given a pamphlet or brief verbal instructions on how to do PFMEs and were told to "lift the pelvic floor" or to interrupt the urinary stream. Although these simple approaches may be adequate for some patients, they do not ensure that patients understand which muscles to use when they begin a structured exercise program at home.

Pelvic Floor Muscle Exercise Regimens

Once patients demonstrate the ability to properly contract and relax the PFMs, they are given instructions for daily practice and exercise. **The purpose of daily exercise is twofold: to increase muscle strength and to enhance motor skills through practice.** Specific exercise regimens vary considerably in frequency and intensity, and the ideal exercise regimen has not yet been determined (Dumoulin et al., 2017; Newman et al., 2018). However, good results have been achieved in several trials using 45 to 60 paired contractions and relaxations per day.

We use an “exercise prescription” to prescribe the daily exercise program (eTable 121.2) (Newman, 2014; Newman and Wein, 2013). One approach is to recommend a series of “quick flicks” or 1- to 2-second contractions, followed by sustained contractions (endurance contractions) of 5 seconds building to 10 seconds. The patient is encouraged to aim for a high level of concentrated effort with each PFM contraction because greater contraction intensity is associated with improvement in PFM strength.

eTABLE 121.2

Sample Pelvic Floor Muscle Exercise Prescription

Please complete the following exercises every day:

1. Short, quick exercise
   Contract the muscle quickly for 1–2 seconds and immediately relax.
2. Long, sustained exercise
   Contract the muscle, and hold the contraction for a count of 5 building to 10 seconds then immediately relax for the same amount of time.
   After each muscle contraction, be sure to rest your muscle for the same amount of seconds.
   When you have completed both types of exercises in all 3 positions, you will have completed one session.

EXERCISE SESSION

Lying Down

Do 5 exercises and squeeze for 1–2 seconds.
Do 5 exercises and squeeze for 5 (building to 10) seconds.

Sitting

Do 5 exercises and squeeze for 1–2 seconds.
Do 5 exercises and squeeze for 5 (building to 10) seconds.

Standing

Do 5 exercises and squeeze for 1–2 seconds.
Do 5 exercises holding for 5 (building to 10) seconds.

- Do 2 exercise sessions each day, one in the morning and one in the evening, for a total of 60 exercises.

SPECIAL TIPS

- Always empty your bladder before starting your exercise session.
- Count out loud when doing the sustained or long exercises so that you make sure you are not holding your breath.
- Keep your stomach, leg, and buttock muscles relaxed. Rest your hand on your stomach. It should not move or tense. Breathing as you contract and relax your muscles will keep your stomach muscle relaxed.
- If it helps, take a deep breath between each exercise to help you keep other muscles relaxed.

Modified from Newman DK, Wein AJ: Office-based behavioral therapy for management of incontinence and other pelvic disorders. *Urol Clin North Am* 40(4):613–635, 2013; Newman DK, Wein AJ: *Managing and treating urinary incontinence,* ed 2, Baltimore, 2009, Health Professions Press, pp 245–306.

It is equally important to relax the PFM completely between each contraction. Each exercise consists of a muscle contraction followed by a period of relaxation using a 1 : 1 or 1 : 2 ratios. This allows the muscles to recover between contractions and facilitates optimal strength building.

It is usually recommended that patients space the exercises throughout the day, typically in 2 to 5 sessions per day to avoid muscle fatigue. Exercising while in the prone position is often recommended at first, because it is the least challenging. However, it is important for patients to progress to sitting or standing positions with time so that they become comfortable and skilled using their muscles to avoid incontinence in any position (Newman et al., 2018).

Use of Pelvic Floor Muscle Contraction to Prevent Stress Incontinence

The goal of behavioral treatment for stress UI is to teach patients how to prevent urine loss in daily life by occluding the urethra using active contraction of PFMs (Miller et al., 1998). **Although exercise alone can improve urethral pressure and structural support and reduce incontinence, this motor skill enables patients to consciously occlude the urethra at specific times when urine loss is imminent.** A careful history or examination of a bladder diary can alert the provider and patient of the circumstances during which each individual patient commonly experiences urine loss. Patients then learn to anticipate these activities and prevent leakage by a volitional contraction of the PFM to occlude the urethra before and during coughing, sneezing, lifting, or any other physical activities that has precipitated urine leakage.

This additional PFM technique uses an anticipatory muscle contraction to preempt a bladder problem at the time of occurrence. This skill has been referred to as the “stress strategy” (Burgio, et al., 1989) and “the Knack” maneuver (Miller et al.1996, 1998, 2008). Miller et al. (1998, 2008) demonstrated immediate reduction in the volume of urine leakage with a cough when an anticipatory PFM contraction was used. Although using this technique requires initial vigilance on the part of the patient and a conscious effort to develop the habit of using muscles to increase urethral closure, it eventually becomes automatic. A handout with instructions for the patient is presented in eTable 121.3.

eTABLE 121.3

Handout for Teaching Stress Strategies and the “Knack”

Urine leakage occurs when the pressure pushing urine out is higher than the pressure holding it in your bladder. Any activity or movement that increases pressure in your abdomen (stomach) may cause you to lose urine. So you may find that you leak urine when you cough, sneeze, stand up, exercise, bend, or lift. If you contract or squeeze your pelvic muscle at the right time, you can prevent a bladder accident or leakage. This is a clever trick or skill you learn, the “knack” for making your pelvic muscle tighten at the right time. You need to anticipate the event or activity that causes leakage and squeeze your pelvic floor muscles before and hold that squeeze through that event. Keeping that muscle tight is what prevents urine from leaking. A bladder diary will help you identify activities that cause leakage.

1. Quickly squeeze your pelvic floor muscles (like trying to hold back gas) just *before and during* the event or activity that normally causes you to leak (cough, sneeze, bending, lifting, getting up from a chair).
2. If you forget to squeeze your muscles and urine leaks out, go ahead and squeeze your muscles right then. It won't prevent that leakage but will help link squeezing the muscles with that activity and help you remember in the future, help you get the “knack” for doing it the next time.
3. This trick takes careful timing and practice. It may take some time for you to get the “knack” of doing it. Don't get discouraged. Eventually, it will become automatic.
4. Remember: “Squeeze before you sneeze.”

Modified from Burgio KL, Pearce KL, Lucco AJ: *Staying dry: a practical guide to bladder control,* Baltimore, 1989, Johns Hopkins Press, pp 67–100; Newman DK, Wein AJ: *Managing and treating urinary incontinence,* ed 2, Baltimore, 2009, Health Professions Press, pp 245–306.

Evidence for Pelvic Floor Muscle Training

PFMT is an established treatment supported by a very large body of evidence (Dumoulin et al., 2017, 2018). A Cochrane review of PFMT-based treatments concluded that these treatments were effective for stress UI and mixed UI (Dumoulin et al., 2014, 2018) and can reduce urgency, but women with pure stress UI may have better outcomes (Bø and Herbert, 2013). PFMT is better than no treatment, a placebo drug, or an inactive control treatment for women with stress, urgency, and mixed UI (Ayeleke et al., 2013; Dumoulin et al., 2017, 2018). Women treated with PFMT show benefit on a number of outcomes, including cure, better quality of life (QoL), reduction in daily leakage episodes, and less urine leakage on a pad or paper towel test immediately after treatment and long term. Cure rates for PFMT range from 16% to 27% and improvement rates from 48% to 80.7%. Evidence is lacking regarding the best approach to PFMT, but **there is consensus that supervised PFMT is more effective than unsupervised programs** (Dumoulin et al., 2017; Hay-Smith et al., 2011, 2012), although the degree and type of supervision needed are uncertain. Moreover, the treatment effect appears to be enhanced when PFMT is based on sound muscle training principles, such as specificity, overload progression, correct contraction confirmed before training, and active use of the PFM to occlude the urethra (referred to as stress strategy or the “knack” contraction).

The effect of PFMT in women with stress UI does not seem to decrease with age; in trials of older women, primary and secondary outcome measures were comparable with those in trials focused on younger women. Thus age should not be a deterrent to PFMT (Betschart et al., 2013). **Based on this evidence, supervised PFMT should be offered as a first-line conservative therapy for women of all ages with stress, urgency, or mixed UI**.

Antenatal Urinary Incontinence

According to a recent Cochrane review, targeting continent antenatal women early in pregnancy and offering a structured PFMT program may prevent the onset of UI in late pregnancy and postpartum (Woodley et al., 2017).

Postpartum Urinary Incontinence

PFMT is recommended during pregnancy and after childbirth for

prevention and treatment of incontinence (Hilde et al., 2013; Mørkved and Bø, 2013; Neilson, 2009; Wesnes and Lose, 2013). Cochrane reviews of randomized or quasi-randomized controlled trials in pregnant or postnatal women included 22 trials involving 8485 women (Boyle et al., 2012, 2014). Postpartum women with UI who were randomized to PFMT taught and supervised by a health care professional were less likely to be incontinent 6 to 12 months after delivery, compared with no treatment or usual care. The ICI committee (Dumoulin et al., 2017) recommends that **PFMT should be offered as first-line therapy to postpartum women with UI persisting 3 months after delivery.** Evidence for the value of perinatal PFMT for the prevention of postpartum UI can be found in eBox 121.3.

Post-Prostatectomy Urinary Incontinence

Stress UI is a complication of radical prostatectomy (RP), regardless of the technique used (Resnick et al., 2013). **PFMT is the primary conservative treatment for UI secondary to prostatectomy.** It may be taught using digital rectal exam with verbal feedback or with BF or E-stim (Mariotti et al., 2009).

Trials of PFMT for established postprostatectomy UI have yielded mixed results but generally show that **PFMT reduces UI in the first 3 months after surgery** (Campbell et al., 2012; Dumoulin et al., 2017). Less research has focused on UI that persists long term. One randomized controlled trial (RCT) compared behavioral training (PFMT + bladder control strategies) versus no treatment in men with UI persisting 1 to 17 years after radical prostatectomy (Goode et al., 2011). After 8 weeks of treatment, men in the behavioral training group showed 55% reduction in UI episodes, significantly greater than the 24% reduction in the control group, and improvements were sustained to 12 months.

According to Dumoulin et al. (2017), it is not clear whether PFMT should be delivered in the form of “hands-on” therapy or verbal instruction. **Current evidence suggests that the addition of PFM E-stim or BF does not appear to improve continence outcomes over PFMT alone. However, BF is an effective approach, and providers may prefer it over digital rectal exam**.

Many studies of postprostatectomy UI involve perioperative PFMT for prevention of post-prostatectomy before UI is established. These studies are covered in eBox 121.3.

Vaginal Cones for Pelvic Floor Muscle Training

Weighted vaginal cones were developed as a method for testing pelvic floor muscle (PFM) function and are sometimes used to **help women identify and control their PFMs** and to support adherence to PFMT (Dumoulin et al., 2017; Herbison and Dean, 2013; eFig. 121.4 for an example of a set of graded weighted vaginal cones). These weighted cones provide progressive muscular overload during strengthening PFM exercises (Peattie et al., 1988). **When a cone is placed in the vagina while standing, the sensation of "losing the cone" provides a strong sensory feedback that prompts the PFM to contract to prevent it from slipping out (**Dumoulin et al., 2017). Women are instructed to insert the heaviest cone they can retain while standing, at first, and then while walking around. When successful with this first cone, they should incrementally increase cone weight and amount of time retaining the cone. The goal is for women to be able to retain the cone using a PFM contraction while walking around for two sessions of 20 minutes per day. The gradual increase in cone weight maintains muscle overload over the course of the exercise program. Some women find the cones helpful and motivating. Others find them uncomfortable, difficult to insert (because of a narrowed vaginal opening), or impossible to retain (because of pelvic organ prolapse [POP] or enlarged vaginal opening). Effectiveness of the cones as a PFMT aid is questionable because orientation of the vagina is not completely vertical; some women can retain the cone without actually contracting the PFMs.

EFIG. 121.4 Example of weighted vaginal cones.

A 2013 Cochrane review (Herbison and Dean, 2013) analyzed 23 trials involving 1806 women, of whom 717 received cones. All of the trials were small, and in many, the quality was difficult to judge. They **concluded that there was some evidence that weighted vaginal cones are better than no active treatment in women with stress UI** and may be of similar effectiveness to PFMT and pelvic floor E-stim. However, more definitive trials are needed to understand the role of weighted vaginal cones in the treatment of UI.

Other Pelvic Floor Muscle Training Devices

The Colpexin sphere is another type of weighted device that women with POP and UI can use for PFMT. It consists of a smooth medical-grade polycarbonate sphere with an attached braided string (eFig. 121.5). It is self-inserted with an applicator or by hand into the vaginal vault and placed within the vaginal canal above the levator musculature (Fig. 121.6). By elevating the prolapse defect, it facilitates the performance of a proper PFM contraction (Deng, 2018). The Colpexin sphere is fitted for each woman based on size (32, 36, 39, 42, and 44 mm) and degree of prolapse and the underlying PFM tone. Similar to vaginal cones, PFM exercises are performed at least twice a day while wearing the sphere. As the PFMs become stronger, the patient can challenge herself by gently tugging on the string while tightening the muscles. In Manonai's et al. (2012) study on the use of the Colpexin sphere in women with stage I or II prolapse in a single-blind RCT, 85 subjects randomized to one of two groups: PFME alone ($n = 45$ control) or Colpexin + PFME ($n = 46$ study group). All women were instructed to perform three sets of exercises daily. Those in the Colpexin group exercised with the device in situ. The intervention duration was 16 weeks. PFM strength was measured using the Colpexin pull test (Jean-Michel et al., 2010) and digitally using the Brink scale, at baseline, 4, 8, 12, and 16 weeks after treatment. There were no significant differences between the two groups in improvement in PFM strength between the two groups at 16 weeks; 85 women (93%, equal in both groups) completed the 16-week assessment with 80% compliance to daily exercise. However, the trial was low risk for selection bias, performance and detection bias, attrition bias, reporting bias, and other bias (Dumoulin et al., 2017). Vaginal symptom score decreased in both groups, while the stages of prolapse did not change (Manonai et al., 2012). Adverse events included vaginal discomfort (85%), vaginal discharge, and abdominal discomfort.

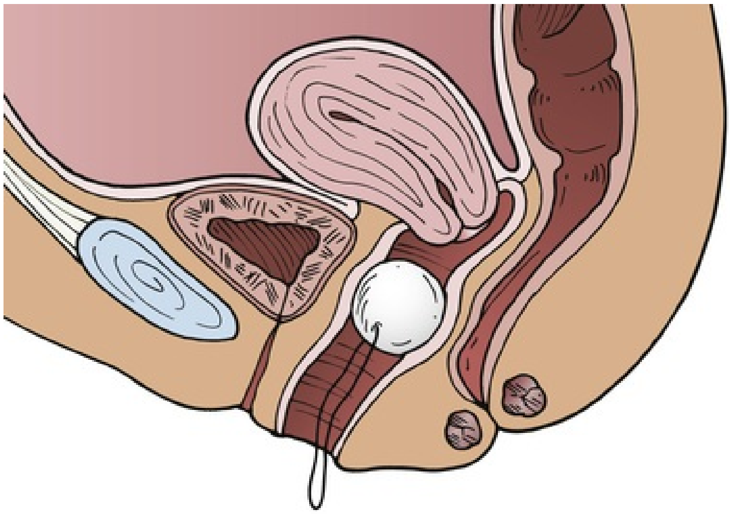

FIG. 121.6 Colpexin sphere vaginal device in place in the vagina.

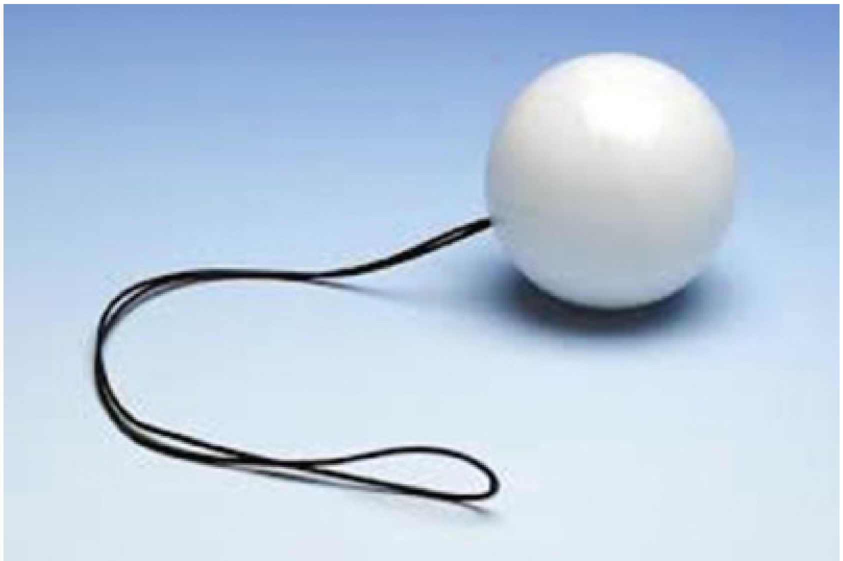

EFIG. 121.5 Colpexin sphere vaginal device.

A critical factor in the outcome of a successful PFMT program is the patient's willingness to perform the exercises correctly and consistently. Theories of motivation emphasize the positive role that perceived competence in a physical activity can intrinsically motivate a person to continue that activity. Research shows that mastering a goal is most strongly related to positive outcomes, such as increased self-perception, autonomous motivation, enjoyment, and behavioral persistence (Keshtidar and Behzadnia, 2017). A successful strategy, used by health care professionals to educate women on their proficiency with PFM exercises, is the use of BF as part of a training device (Newman, 2014). Delgado et al. (2013) noted that the use of a PFMT device (pelvic floor trainer) appeared to help women gain confidence that they were doing the exercises properly plus motivated them to continue.

Technologic advancements, including smart phone applications, have resulted in the availability of numerous home-based PFMT devices for women (Araujo et al., 2019; Starr et al., 2016). Many purport to aid women in performing PFMEs properly. A systematic review of available mApps for PFMT by Latorre et al. (2019) concluded that this technology has potential to improve adherence. Dr. Kegel described a vaginal pressure device (a perineometer) for PFMT that was connected to a manometer, “devised specifically for the exercise of birth canal muscles, with measurement of each muscular contraction visible to the patient” (Kegel, 1948; eFig. 121.7). Ong et al. (2015) conducted a pilot prospective study to compare the effectiveness of doing PFMEs with and without a pelvic trainer device (Fig. 121.8). Forty women (≥age 18) with stress UI were enrolled in a control group (PFME alone, $n = 19$) or to the pelvic trainer group (PFME with the device, $n = 21$). Both groups underwent 16 weeks of training, and PFM strength testing at weeks 0, 4, and 16. In the control group three women (15.8%) withdrew during week 16. The women in the device group had significant improvement in stress UI scores ($P = 0.35$) at week 4 but no significant differences between the two groups at week 16. PFM strength was better in the pelvic trainer device at week 4 ($P = 0.025$) and week 16 ($P = 0.001$).

Many of these devices fall short in offering progressive resistance and accurate feedback with standardized instruction. The need exists for a practical and safe PFMT device with these features to better instruct and motivate women with UI and LUTS in performing in-home PFMEs correctly and consistently.

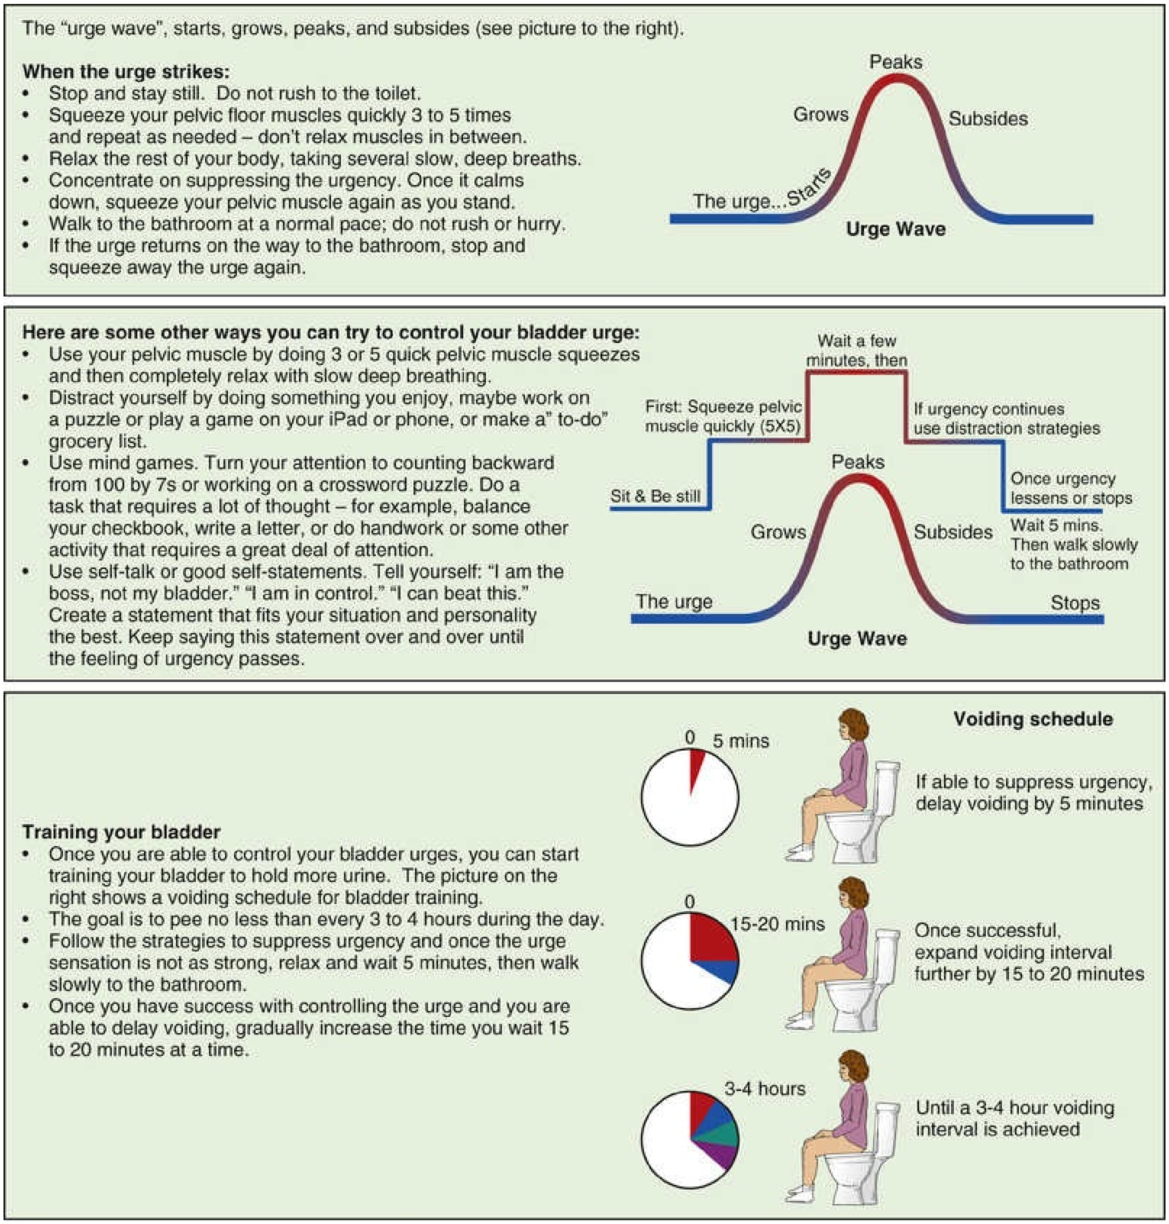
Behavioral Training With Urge Suppression

Behavioral training is a stand-alone treatment that teaches patients how to use their PFMs to inhibit a detrusor contraction and how to use this skill as a part of a larger urge-suppression strategy that constitutes a new way of responding to urge for patients with urgency, frequency, and/or urgency UI. Behavioral training evolved out of BF-assisted behavioral training in which bladder and anal sphincter BF were used together to teach patients to inhibit a detrusor contraction during retrograde bladder filling. Originally, the focus of training was on bladder pressure feedback and learning cortical inhibition of detrusor contraction. During these BF sessions, it was observed that spontaneous anal sphincter activity appeared to affect detrusor pressures, and it was subsequently demonstrated that **a well-timed, volitional contraction of the anal sphincter (reflecting PFM), guided by visual BF, could abort fully developed detrusor contractions, deter developing contractions, and suppress the sensation of urgency** (Burgio et al., 1986, 1998).

Later, it was shown that this skill could be taught without BF, using verbal feedback based on vaginal palpation instead. In a randomized trial of behavioral training with and without BF, older women with urgency UI, taught using verbal feedback based on vaginal palpation, achieved outcomes as good as those achieved using bladder-sphincter BF when this skill was integrated into a larger strategy (Burgio et al., 2002).

Based on these findings, **although PFMT and PFME were originally designed for the treatment of stress UI, they are now used as central elements in the treatment of urgency UI and OAB.** In behavioral training, patients are taught PFM control and exercise in the same way as for stress UI. What differs is how they use their muscles to manage urgency and prevent urine loss. In addition to using the PFM to occlude the urethra, patients learn to use PFM contractions as one part of a broader strategy to respond to the sensation of urge. Urge-suppression strategies with emphasis on incremental increases in voiding intervals are an integral part of BT, which is discussed later in this chapter.

Patients with urgency and urgency UI often feel compelled to rush to the nearest bathroom when they feel the urge to void, believing that they are about to lose control. **With behavioral training, they learn how this natural “gotta go” response is actually counterproductive** because it increases physical pressure on the bladder, increases the feeling of fullness, exacerbates urgency, and triggers detrusor contraction. Further, as the patient approaches the toilet, visual cues can trigger urgency and incontinence. To avoid this conditioned response, **patients are taught not to rush to the bathroom when they feel the urge to void. Instead, they are advised to stay away from the bathroom so as to avoid exposure to cues that trigger urgency** (Burgio et al., 1989). They are encouraged to pause, sit down if possible, relax the entire body, and contract PFMs repeatedly, without relaxing in between contractions, to diminish urgency, inhibit detrusor contraction, and prevent urine loss. They focus on inhibiting the urge sensation, giving it time to pass. Once the sensation subsides, they walk at a normal pace to the toilet. (A handout for teaching the urge-suppression strategy and BT is in Fig. 121.9.)



The “urge wave”, starts, grows, peaks, and subsides (see picture to the right).

When the urge strikes:

- Stop and stay still. Do not rush to the toilet.
- Squeeze your pelvic floor muscles quickly 3 to 5 times and repeat as needed – don’t relax muscles in between.
- Relax the rest of your body, taking several slow, deep breaths.
- Concentrate on suppressing the urgency. Once it calms down, squeeze your pelvic muscle again as you stand.
- Walk to the bathroom at a normal pace; do not rush or hurry.
- If the urge returns on the way to the bathroom, stop and squeeze away the urge again.

Subsides
The urge...Starts
Urge Wave

Here are some other ways you can try to control your bladder urge:

- Use your pelvic muscle by doing 3 or 5 quick pelvic muscle squeezes and then completely relax with slow deep breathing.
- Distract yourself by doing something you enjoy, maybe work on a puzzle or play a game on your iPad or phone, or make a” to-do” grocery list.
- Use mind games. Turn your attention to counting backward from 100 by 7s or working on a crossword puzzle. Do a task that requires a lot of thought – for example, balance your checkbook, write a letter, or do handwork or some other activity that requires a great deal of attention.
- Use self-talk or good self-statements. Tell yourself: “I am the boss, not my bladder.” “I am in control.” “I can beat this.” Create a statement that fits your situation and personality the best. Keep saying this statement over and over until the feeling of urgency passes.

Wait a few minutes, then
First: Squeeze pelvic muscle quickly (5X5)
If urgency continues use distraction strategies

Urge Wave

Training your bladder

- Once you are able to control your bladder urges, you can start training your bladder to hold more urine. The picture on the right shows a voiding schedule for bladder training.
- The goal is to pee no less than every 3 to 4 hours during the day.
- Follow the strategies to suppress urgency and once the urge sensation is not as strong, relax and wait 5 minutes, then walk slowly to the bathroom.
- Once you have success with controlling the urge and you are able to delay voiding, gradually increase the time you wait 15 to 20 minutes at a time.

Voiding schedule

If able to suppress urgency, delay voiding by 5 minutes

Once successful, expand voiding interval further by 15 to 20 minutes

Until a 3-4 hour voiding interval is achieved

FIG. 121.9 Patient handout with instructions for the urge-suppression strategies and bladder training. (Adapted from Newman, Borello-France & Sung, 2018; Burgio et al, 1989; Wyman & Fantl, 1991; Newman and Wein, 2009, 2013.)

Once patients master the urge-suppression strategy, they are encouraged to delay voiding for 5 minutes to consolidate their skill. If they are voiding too frequently, this delayed voiding interval can be increased gradually until they achieve a normal voiding frequency.

The effectiveness of behavioral training with urge suppression as a stand-alone therapy for urgency UI has been established in several clinical series studies and in RCTs using intention-to-treat models, in which mean reductions of incontinence range from 60% to 80% (Burgio et al., 1998, 2002). In one RCT, behavioral training reduced incontinence episodes significantly more than individually titrated drug treatment, and patient perceptions of improvement and satisfaction with their progress were higher (Burgio et al., 1998).

This therapy has also been shown to reduce urgency, frequency, and nocturia in men and women. As an example, the Male Overactive Bladder in Veterans (MOTIVE) study compared behavioral training with urge suppression to antimuscarinic therapy (extended-release oxybutynin) in men with OAB in the absence of bladder outlet obstruction (Burgio et al., 2011). Mean 24-hour voids decreased significantly in both groups, and these reductions were statistically equivalent. In another trial, 24-voiding frequency was lower after treatment when compared with combination drug therapy (anti-muscarinic + an alpha blocker) (Burgio et al., 2018).

Behavioral training with urgency suppression has also been shown to reduce nocturia in men and women (Burgio et al., 2011; Johnson et al., 2005, 2013, 2016). Patients are instructed to use urge-suppression techniques when they wake up at night with bladder fullness or an urge to void. If the fullness/urge subsides, they are encouraged to go back to sleep. If after a minute or two the urge to void has not subsided, they are advised to get up and void, so as not to interfere unnecessarily with their sleep. Johnson et al. (2005) showed that behavioral training and drug therapy reduced nocturia more than placebo in women, and behavioral training was significantly more effective than drug therapy. In a study in men with OAB (Johnson et al., 2013), behavioral treatment (PFMT, delayed voiding, and urge-suppression techniques) and drug (antimuscarinic) therapy reduced nocturia in men when added to alpha-blocker therapy, but the addition of behavioral treatment was statistically better than the addition of antimuscarinic therapy for nocturia. In a trial with men with nocturia, behavioral training, alone or combined with alpha-blocker therapy, showed large and statistically significant nocturia reductions (Johnson et al., 2016).

There is also evidence that combining behavioral training with drug therapy can improve outcomes of drug therapy for urgency UI. In a multi-site trial conducted by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) Urinary Incontinence Treatment Network, women with urge-predominant incontinence were randomized to receive extended-release tolterodine with or without behavioral training. Women who underwent behavioral training in addition to drug therapy reported greater improvements on patient perception of improvement, patient satisfaction, and validated measures of symptom distress and bother while on active therapy, as well as 6 months after drug therapy was discontinued (Burgio et al., 2008). In an RCT of combined behavioral and drug therapy in men with voiding frequency, mean voiding frequencies after treatment were significantly lower in the combined therapy group compared with the drug alone but not significantly lower than the behavioral-alone group. Further, combined therapy yielded the best results on secondary outcomes, including patient perception of improvement and satisfaction (Burgio et al., 2018).

In addition to be a central element of behavioral training, the urge-suppression strategy has also been adopted as one of several techniques to help patients postpone voiding in BT or delayed voiding programs.

Role of Biofeedback

BF is not a treatment but a technique for teaching patients control over physical responses. Commonly known for its role in treatment of headaches, muscle spasm, and hypertension, it is also a very effective method for teaching bladder and PFM control in the treatment of LUTS. **BF helps patients learn by giving them precise, instantaneous feedback of their physiologic responses, such as PFM contraction.** The “perineometer” (see eFig. 121.7) developed by Dr. Kegel was a BF instrument that assisted women to learn PFM control by giving women immediate feedback of efforts to contract PFMs. BF may be especially helpful in patients who are having difficulty identifying and isolating the correct muscles, to track PFM strength during treatment or who need encouragement to continue with prescribed treatment.

Most BF instruments are now computerized and display feedback visually on a monitor (Fig. 121.10). **PFM activity can be measured by manometry or surface electrode electromyography (sEMG),** using vaginal or anal probes or surface skin electrodes. Signals are enhanced through the computer, and feedback is provided on a monitor for visual feedback (eFig. 121.11) or via speakers for auditory feedback. When patients observe the results of their attempts to control PFM muscle activity (Fig. 121.12 and eFig. 121.13), learning occurs by means of operant conditioning (trial and error learning).

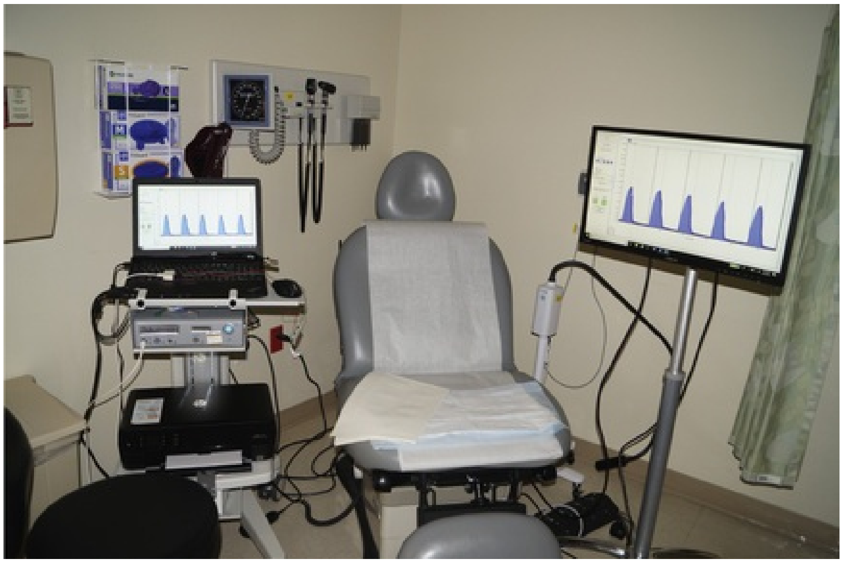

FIG. 121.10 Prometheus biofeedback equipment with monitors for visual

feedback.

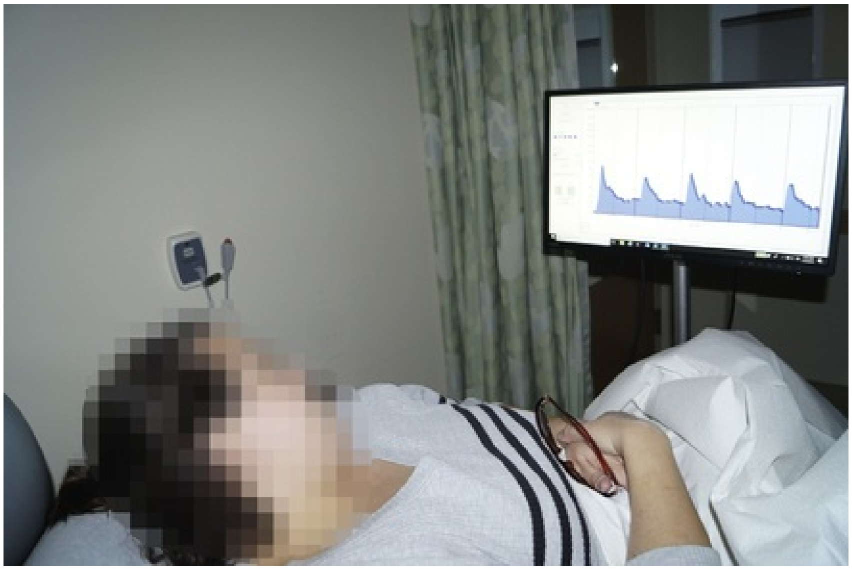

FIG. 121.12 Female patient reclining to view biofeedback monitor while contracting pelvic floor muscles.

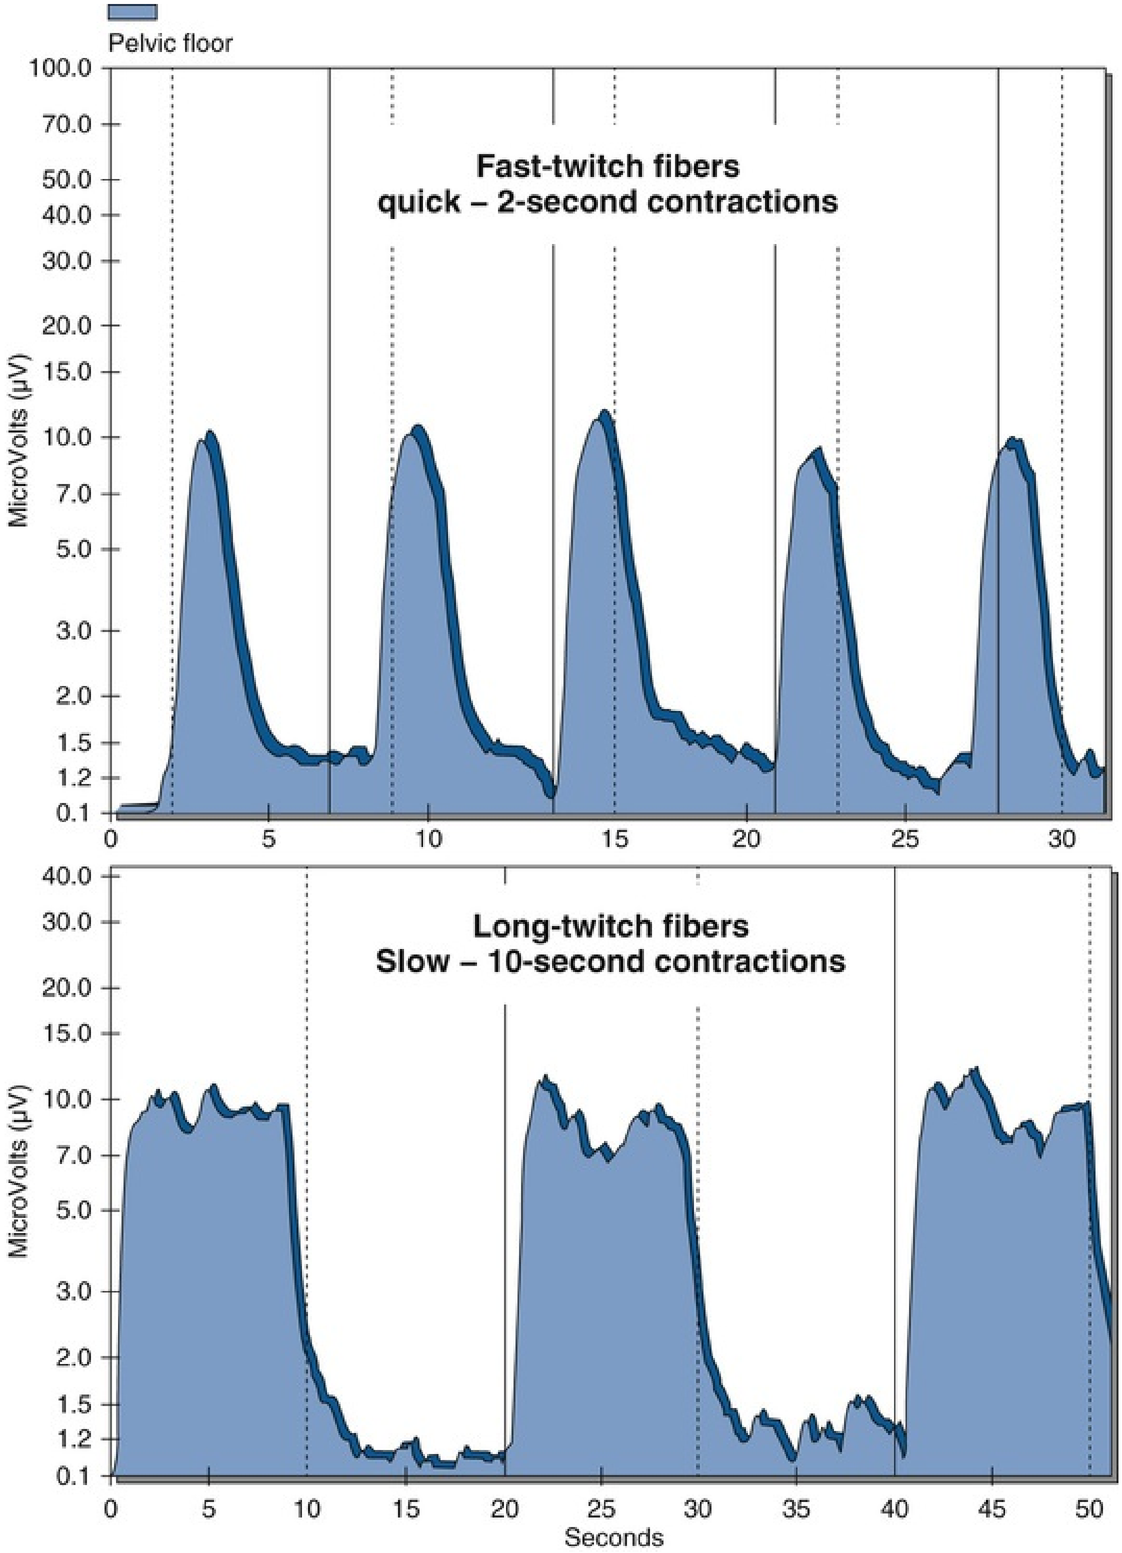

EFIG. 121.11 Biofeedback graph showing quick and long contractions.

EFIG. 121.13 Male patient sitting to view biofeedback monitor while contracting pelvic floor.

An advantage of EMG over manometric pressure is that, provided the machinery is of sufficient sophistication with adequate filtering, EMG apparatus can use the newer types of electrodes that are lightweight and designed to stay in place, therefore allowing more functional positions during assessment and treatment. Like other methods, EMG can be multi-channel, which allows the simultaneous display of PFM contraction and inhibition of counterproductive accessory muscle contractions (e.g., abdominal, gluteal muscle).

BF-assisted PFMT in conjunction with other conservative treatment components has been tested in several studies, producing mean reductions of UI ranging from 60% to 85% (Dumoulin et al., 2017). BF technology is an excellent method to help patients identify and exercise PFMs, but it is not the only effective method. **The literature is inconsistent on the issue of whether BF enhances outcomes of PFMT.** A 2011 Cochrane review (Herderschee et al., 2011, 2013) included 24 trials involving 1583 women and concluded that women who received PFMT with BF were significantly more likely to report cure or improvement compared with those who received PFMT alone. However, these studies should be interpreted cautiously because the treatment groups differed on parameters other than BF, such as preparation of the clinician providing the therapy, and women in the BF groups usually had more extensive contact with providers. Urology and urogynecology practices who offer conservative behavioral treatments and physical therapists who specialize in PFM rehabilitation commonly use BF as part of PFMT (Newman, 2014;

Newman and Wein, 2013; Schmitt et al., 2017; Starr et al., 2013, 2016).

Pelvic Floor Muscle Electrical Stimulation

PFM E-stim with a non-implanted device involves the application of a low grade of E-stim to the PFMs to stimulate a contraction in patients with different types of UI or symptoms of urgency, frequency, and nocturia (Newman and Wein, 2009). **E-stim has a twofold action: contraction of PFMs and inhibition of unwanted detrusor contractions** (Schreiner et al., 2013). E-stim is provided by office-based machines or portable battery-powered stimulators that are used in the medical office or by the patient at home. These units have different combinations of current types, waveforms, frequencies, intensities, electrode types, and placements.

Pelvic floor muscle E-stim is usually a component of conservative treatment in PFM rehabilitation practices; clinicians use it to assist in PFM identification (Starr et al., 2013). Patients with LUTS secondary to neurologic disease (e.g., multiple sclerosis) may also benefit from this treatment because E-stim can build muscle strength. Many clinicians institute this treatment in patients who have failed other behavioral and medical treatments and prescribe home units for long-term treatment. **There are two main types of E-stim:**

1. Long-term or chronic E-stim delivered below the sensory threshold aiming at detrusor inhibition by afferent pudendal nerve stimulation. According to Fall and Lindstrom (1994), the electrically evoked activity results in reflex activation of hypogastric efferents and central inhibition of pelvic efferent mechanisms sensitive to low-frequency stimulation. The device is used for 6 to 12 hours per day for several months.
2. Maximal E-stim, using a high-intensity stimulus (just below the pain threshold), aims to improve urethral closure by direct and reflexogenic contraction of striated peri-urethral musculature (Fall et al., 1991). Detrusor inhibition by afferent pudendal nerve stimulation has also been suggested as a mechanism (Berghmans et al., 2002). This type of E-stim is applied for short durations (15 to 30 minutes) several times a week (or one to two times daily using portable devices at home).

In the context of conservative therapy, E-stim is delivered transcutaneously via suprapubic, sacral, or external anal skin surface electrodes or intravaginal or intrarectal sensors. Parameters for E-stim include current source, pulse width and duration, current intensity (range), stimulus frequency, pulse shape, length of session, total number of sessions, and rest-to-work ratio, which are varied according to type of UI and type of electrical stimulation. Berghmans et al. (2002) reported that frequencies of 5 to 20 Hz are usually used for urgency UI, 20 to 50 Hz for stress UI (including post-prostatectomy), and for mixed UI around 20 Hz or high and low frequency alternately. Pulse durations range from 200 to 1000 µsec. The pulse shape is generally rectangular, and biphasic pulses are preferred.

The literature indicates that E-stim is effective for improving stress UI in women (Stewart et al., 2017) **and for urgency and mixed UI compared with sham or no treatment (**Dumoulin et al., 2017)**. However, it does not appear to enhance outcomes over those obtained through PFMT alone or PFMT with BF.** Less work has been done examining E-stim in men (Berghmans et al., 2013; Goode et al., 2011), and there is **little evidence to suggest that E-stim improves outcomes of PFMT, with or without BF, but it may hasten the recovery of continence after prostatectomy.**

Bladder Training and Scheduled Voiding Regimens

Scheduled voiding regimens, also known as toileting programs, have for decades been a mainstay of treatment for urgency UI and OAB. Scheduled voiding regimens include BT, timed voiding (TV), habit training (HT), and PV (eTable 121.4). Although these regimens share the common feature of being based on a toileting schedule, they differ on the role of the patient (active vs. passive), how adjustments are made to the voiding schedule, the nature of patient education, the use of reinforcement techniques, and the nature of the patient-provider interaction (Dumoulin et al., 2017). BT is self-administered and requires the patient to resist urgency and delay voiding. TV, HT, and PV most often rely on caregiver involvement.

eTABLE 121.4

Understanding Toileting Programs

TYPE	DEFINITION	KEY COMPONENTS
Timed voiding (or scheduled toileting)	Fixed, predetermined time intervals between toileting	The following is an example of a toileting program that can be used by institutions or caregivers that includes 8 times in a 24-hour period, or every 3 hours: • Day: Upon awakening, after breakfast, mid-morning, before lunch, and after an afternoon nap (mid-afternoon) • Evening: Before dinner and at bedtime • Night: Determine if person wants to be awakened at night to void and identify times.
Habit training	Fixed voiding schedule based on identified patterns of incontinence to pre-empt incontinence	Using a bladder diary, incontinence and voiding patterns are identified and an individualized toileting schedule is developed. In institutions such as nursing homes, a typical toileting schedule may be determined around daily events.
Prompted	Involves prompting and	The major elements of prompted

voiding	assisting patients to toilet and positive reinforcement for requesting toileting assistance either spontaneously or following verbal prompts from a caregiver	voiding are the following: • Monitoring: The caregiver checks on a regular basis (use toileting schedule described in scheduled toileting) and person is asked to report verbally if wet or dry. • Prompting: The person is asked if they need to void and assisted with voiding. • Praise and encouragement: The caregiver provides these if the person is continent. Most successful in individuals who can ask for assistance or void when prompted.
Functional incidental training	Combines prompted voiding with functionally oriented, low-intensity endurance and strength-training exercises	Combines mobility and transfer training with prompted voiding
Bladder training	Training involves establishing a voiding schedule and incrementally increasing the voiding interval	Promotes restoration of normal bladder function through incremental voiding schedules and education regarding urge inhibition techniques. Requires person to be able and willing to participate actively. Four primary components: 1. Education program that usually combines written, visual, and verbal instruction addressing the physiology and pathophysiology of the lower urinary tract 2. Scheduled voiding with systematic delay of voiding that requires the ability to resist or inhibit the sensation of urgency to postpone voiding and to urinate according to a timetable rather than according to the urinary urge 3. Use of techniques to suppress urgency (quick PFM contractions, deep breathing with relaxation, distraction techniques) 4. Gradual increases in voiding interval 5. Reinforcement through consistent encouragement and positive feedback

Modified from Flanagan L, Roe B, Jack B, et al.: Systematic review of care intervention studies for the management of incontinence and promotion of continence in older people in care homes with urinary incontinence as the primary focus (1966-2010). *Geriatr Gerontol Int* 12(4):600–611, 2012; Newman DK, Burgio KL, Markland A D, Goode PS: Urinary incontinence: nonsurgical treatments. In Griebling TL, editor: *Geriatric urology,* London, 2014, Springer-Verlag, Ltd, p 142; Newman DK, Wein AJ: *Managing and treating urinary incontinence,* ed 2, Baltimore, 2009, Health Professions Press, pp 245–263.

Bladder Training

BT is a behavioral intervention developed originally for the treatment of urgency UI. Many patients who experience urgency UI or urgency without leakage tend to void frequently. This response provides immediate relief from the sensation of urgency, but it sets the stage for more and more frequent urination. Once frequent voiding becomes a habit, it can be difficult to change and may lead to reduced functional bladder capacity, detrusor overactivity, and in some cases, urge UI. Detrusor overactivity produces urgency, completing a cycle of urgency and frequency that is then perpetuated. **This cycle can be broken using BT or a program of progressive delayed voiding.**

The goal of BT is to restore normal bladder function and capacity using consistent, incremental voiding schedules. First known as bladder drill, it was an intensive intervention that was often conducted in an inpatient setting. Now the program is implemented more gradually in an outpatient setting. **Bladder training is a multi-component intervention that involves patient education regarding lower urinary tract function, setting incremental voiding schedules, and teaching urge control techniques to help patients postpone voiding and adhere to the schedule** (Fantl et al., 1991; Wallace et al., 2009; Wyman and Fantl, 1991).

Usually BT begins with the patient completing a bladder diary to document voiding patterns and frequency. Based on the diary, an initial voiding interval is established (Dumoulin et al., 2017). Often, this is a 1-hour interval during waking hours, although a shorter interval (e.g., 30 minutes or less) may be necessary at first. Another method is for the clinician to select a voiding interval based on the longest time interval between voids that is comfortable for the patient. The patient is to void upon waking in the morning, every time the interval has passed, and just before bedtime. The schedule is increased by 15 to 30 minutes per week depending on the patient's tolerance of the schedule (i.e., fewer incontinent episodes than the previous week, minimal interruptions to the schedule, and the individual's control over urgency) (see Fig. 121.9).

In BT the patient is asked to postpone urination, which for most patients involves coping with the sensation of urgency while they wait. **The approach used in clinical practice to manage urgency has been to suggest various techniques for relaxation or distraction to another activity** (Fantl et al., 1991, Wyman, 2007; Wyman and Fantl, 1991). Patients are encouraged to get their mind off the bladder by engaging in an activity that requires mental but not physical effort (see Fig. 121.9).

Common activities include playing a game on a mobile device such as an iPad or phone, reading, or making a to-do list. Distracting attention from the bladder in this way can reduce anxiety and allows time for the urge to subside. Also used are affirming self-statements such as “I am in control of my bladder,” or “I can wait.”

Another method for postponing urination is performing a few quick PFM contractions. Shafik and Shafik (2003) demonstrated detrusor relaxation in response to a PFM contraction in men and women with OAB ($n = 28$) and without ($n = 17$). They hypothesized the quick muscle contraction created a mechanical compression of the urethra for a few seconds causing inhibition of a detrusor contraction leading to reduced desire to void. **So repeated rapid contractions of the PFM (termed “quick flicks”) with the individual remaining posturally still and waiting for the sensation to pass (urge suppression) has proven to be a useful adjunct to BT regimen for OAB** (Dumoulin et al., 2017; Newman et al., 2018; Newman and Wein, 2009).

Ideally, the clinician should monitor a patient's progress on a weekly basis during the training period, make individualized adjustments to the voiding interval, and provide positive reinforcement during the training period. **Patient self-monitoring using voiding diaries is a useful tool to help the patient and clinician evaluate adherence to the schedule, evaluate progress, and determine whether the voiding schedule should be changed.**

The underlying mechanisms of how BT works are unknown. However, one of the most important features of BT is that it dissociates voiding from urgency, and it may be that voiding by the clock, rather than in response to urgency, weakens the urge-void response. Other hypotheses include improved cortical control of bladder activity and urethral closure, improved central modulation of afferent stimuli, altered behavior because of better awareness of lower urinary tract function, and increased bladder capacity.

Evidence for Bladder Training

Several systematic reviews have been published that provide synthesis and grading of evidence for BT in the treatment of UI or urgency UI (Berghmans et al., 2002; Dumoulin et al., 2017; Fantl et al., 1996; Moore et al., 2013; Roe et al., 2007, Wallace et al., 2009). The ICI included RCTs with participants who had UI (urgency, stress, and mixed), as well as participants who had OAB without UI. Based on 17 trials involving 2462 women and five trials with 142 men, the ICI noted and described remarkable variability in BT protocols and concluded that there was no evidence to suggest the most effective method or specific parameters of BT. However, they **recommend that clinicians provide the most intensive BT supervision possible within service constraints** (Dumoulin et al., 2017).

From the few trials available of BT **in women with urgency UI, stress UI, and mixed UI, the ICI concluded that BT is more effective than no treatment, but there was insufficient evidence to draw conclusions on its effect in men. They also found insufficient evidence to draw conclusions on the comparative effectiveness of BT and current drug therapy, or for their combined effectiveness for women with detrusor overactivity or urgency UI.**

In a comparative effectiveness review of nonsurgical treatments for UI in women, the Agency for Healthcare Research and Quality (AHRQ) (Shamliyan et al., 2008) found that UI outcomes did not differ between BT and PFMT, nor were there differences between BT alone and BT combined with PFMT.

Other Scheduled Voiding Regimens

Toileting programs are the cornerstone of continence care for cognitively impaired patients. Other than BT, toileting programs are usually “caregiver dependent,” defined as the need for a professional or family caregiver to assist with toileting (Newman and Wein, 2009). **Scheduled voiding can be beneficial for toileting-dependent residents in nursing homes or individuals living at home who have an available and willing caregiver.** Individuals who have difficulty or require human or mechanical assistance with toileting are referred to as having “toileting disability” (Talley et al., 2014). These individuals may have mobility or cognitive impairment, may need some assistance from at least one person, but are able to cooperate with toileting. The choice of timed voiding, habit training, or a prompted voiding program is determined by the cognitive and functional status of the individual, the variability of the voiding pattern, and the need for reinforcement for adherence to the regimen.

Timed Voiding

Timed voiding (TV) has also been called scheduled toileting, routine toileting, and fixed toileting. **The goal of TV is to prevent incontinence by providing regular opportunities for bladder emptying before the bladder reaches capacity.** Keeping the bladder volume below capacity may decrease leakage associated with a detrusor contraction that occurs with a full bladder, as well as decrease leakage that may occur with stress UI. No other physiologic mechanism has been determined. TV has been recommended for patients who cannot toilet independently. It has been **used primarily in institutional settings as a passive toileting assistance program, in which a caregiver takes the patient to void every 2 to 4 hours except at night, and for patients with neurogenic bladders associated with spinal cord injuries** (Ostaszkiewicz et al., 2004a, 2005a,b). Ideally, the schedule for toileting is based on some objective measure, such as a bladder diary, on data collected using a bladder volume recording instrument (Newman et al., 2005; Suzuki et al., 2019), or from an electronic device used to monitor and record incontinence episodes (Colling et al., 2003).

TV is a “passive” type of toileting program, because it takes place whether or not the patient has a sensation to void, but the schedule is usually only followed during waking hours (Ostaszkiewicz et al., 2005a,b). The goal is to keep the person dry, and no effort is made to motivate the person to resist the urge to urinate. **Although fewer than 20% of frail elders become completely dry with TV, between 30% and 50% of incontinent elders may improve,** reducing the number and volume of incontinence episodes. This is probably also true in people being cared for in their homes.

TV can also be useful for cognitively intact elders who have developed bladder sensory impairment because of neurologic conditions. Voiding by the clock, instead of waiting for urgency, and before spontaneous bladder emptying occurs, can prevent or reduce incontinence. A brief, 2- to 3-day trial of timed voiding can determine if it will be successful for an individual. TV is also intended to normalize frequency in a patient with infrequent voiding and/or diminished sensation (Payne, 2012).

Habit Training

Habit training (HT) is a variant of TV, with the difference being that the **toileting**

schedule is matched to the patient's voiding pattern, rather than being fixed as it is in TV. Using the patient's bladder diary, a toileting schedule is assigned to fit a time interval that is shorter than the patient's normal voiding pattern and to precede the time period when incontinent episodes are expected. Thus the voiding interval may be lengthened or shortened throughout the day depending on the patient's voiding pattern with the goal to preempt incontinence. In the traditional applications of HT, **it is a caregiver-dependent toileting assistance program that is initiated and maintained by the active involvement of a professional or family caregiver** (Ostaszkiewicz et al., 2004b).

HT has primarily been used in institutional settings with cognitively and physically impaired adults; but it also has been tested with the homebound elderly population (Colling et al., 2003). The interval may be set permanently or gradually increased.

Colling et al. (2003) developed an HT program called pattern urge-response toileting (PURT) and tested it with 78 caregiver-dependent (relatives, primarily spouses) homebound frail elders. Three weeks of voiding patterns were obtained from electronic data logs; individualized toileting schedules were identified based on each person's voiding pattern; and caregivers were taught when and how to toilet the care recipient. The PURT program reduced the number of incontinent episodes over 24 hours by 18%, decreased the mean number of daily episodes from 4.9 to 4.0, and reduced the volume of UI over 24 hours by 39%.

Prompted Voiding

Prompted voiding (PV) is a toileting program that combines scheduled voiding with "prompting" from a caregiver with contingent social approval (Wagg et al., 2017). **It is used to teach people with or without cognitive impairment to initiate their own toileting through requests for help and positive reinforcement from caregivers when they do so.** It has been used primarily in nursing home settings with cognitively and physically impaired older adults (Burgio et al., 1994; Eustice et al., 2000; Schnelle et al., 1989) as well as in home care settings (Engberg et al., 2002).

Prompted voiding has **three components:** (1) regular monitoring with encouragement to report continence status, (2) prompting of the individual to toilet on a scheduled basis, and (3) praise with positive feedback when the individual is continent and tries to toilet (Lekan-Rutledge, 2000; Lyons and Specht, 2000). PV is appropriate for older adults with urgency, mixed, or functional UI and includes cognitively intact and impaired individuals

(Newmanet al., 2018). The main requirement of PV is the *consistent* availability of a caregiver to provide the voiding prompts to incontinent individuals. For PV to be effective, individuals must be able to delay voiding and cooperate with toileting or have awareness of when they need to void.

A systematic review (Flanagan et al., 2012) of four RCTs from 1996 to 2010 of **the management of incontinence in care homes using PV showed a decrease in incontinent episodes.** PV has been shown to be effective in the short-term treatment of daytime UI in nursing home residents and home care clients when caregivers comply with the protocol (Wagg et al., 2017). The majority of the research has shown that between 25% and 40% of incontinent nursing home residents respond well to toileting assistance, whereas approximately 38% cannot successfully toilet, even when provided help by research assistants (Ouslander et al., 1995a). In one study of 191 incontinent residents in seven nursing facilities, 25% to 40% responded well to PV during the day, with incontinence episodes decreasing from three or four during the day to one or none.

Ouslander et al. (2005) combined PV with other activities of daily living, as part of a multi-component intervention known as functional incidental training (FIT). FIT used a “designated” versus “integrated” nursing assistant role to combine restorative care including a walking program, exercise therapy, and continence care. This intervention has repeatedly been shown to improve physical function, as well as UI in nursing facility residents (Ouslander et al., 2005; Schnelle et al., 1995). A 3-day trial of PV can demonstrate whether or not it is likely to be effective (Ouslander et al., 1995a).

Lai and Wan (2017) conducted an RCT to examine the effectiveness of the use of PV by nursing home staff in managing UI among residents in five nursing homes in Hong Kong over a 6-month period. There were significant differences between the two groups in wet episodes per day, incontinence rate per day, and total continent toileting per day at 6 months’ post-intervention. A decrease of 9.1% was observed in the incontinence rate of the intervention group. The PV program delivered by staff was sustainable for a 6-month period.

Another method to individualize PV is through the use of bladder volume instruments to scan the bladder to determine amount of urine in the bladder. Suzuki et al. (2019) conducted an RCT in 13 nursing homes in Japan and compared the efficacy and feasibility between ultrasound-assisted prompted voiding (USAPV) and conventional prompted voiding (CPV) in decreasing daytime urine loss in residents with UI. Residents were randomized to either a

CPV (*n* = 7) or USAPV group (*n* = 6). Over an 8-week period, staff conducted PV every 2 to 3 hours on the CPV group, but in the USAPV group, staff monitored bladder volume using an ultrasound device and prompted the resident to void when the volume reached optimal bladder capacity. Measurement of urine loss was recorded using a frequency-volume bladder chart at baseline and after the 8 weeks. The change in daytime urine loss was greater in the USAPV (median, −80 g) than in the CPV group (median, −9.0 g; $P = 0.18$). At the end of the 8 weeks, daytime urine loss less than 25% was seen in 51% of the USAPV group and only in 26% of the CPV group ($P = 0.010$). However, QoL measures were unchanged in either group. Caregiver burden scale score worsened in the CPV group.

Challenges of Caregiver-Administered Voiding Schedules.

The impact of a toileting regimen on caregivers can be significant (Roe et al., 2011). **UI management has been rated as the third most troublesome caregiving task,** behind a lack of time for their own needs and managing the care recipient's emotional and behavioral problems (Colling et al., 2003). Engberg et al. (2002) reported areas of caregiver strain in relation to incontinence, including odor (56%), toileting (55%), changing pads and clothing (53%), UI-related costs for pads or briefs (53%), wet clothing (50%), and changing bed linens (44%). Drennan et al. (2012) conducted a qualitative study of managing incontinence for people with dementia living at home and found that toilet prompting or reminding can lead to irritation and arguments because patients perceive this as being treated like a child.

Delayed Voiding

Delayed voiding is another approach to helping patients to expand the interval between voids. It differs from BT in that patients are not placed on a predetermined voiding schedule. When first experiencing an urge to void, patients are instructed to use their urge-suppression techniques until the urge subsides. However, instead of going to the bathroom immediately after suppressing the urge, they postpone urination by waiting 5 minutes before voiding. This technique can be used in combination with other behavioral components (BT, PFMT, urge suppression) to reduce excessive voiding frequency (Burgio et al., 2011).

In patients who have experienced urgency UI, even a mild urge to void triggers a trip to bathroom as soon as possible because of the fear of leakage otherwise. However, most patients can be convinced to try a 5-minute delay, particularly in safe circumstances such as being at home alone. Often, they are surprised to find that after a brief wait, the urge subsides or disappears altogether. This enhances their sense of control and helps restore confidence so that they can gradually increase the delay time to achieve a normal frequency.

Behavioral Treatment for Voiding and Pelvic Floor Dysfunction

Pelvic floor muscle dysfunction, especially PFM overactivity (high-tone PFM dysfunction), is characterized by elevated resting tone (hypertonicity) and decreased relaxation capacity. It manifests in such symptoms as pelvic floor tenderness/pain, bladder pain syndrome, and/or voiding symptoms, including hesitancy, straining to void, and incomplete bladder emptying. Assessment includes digital palpation of the PFMs to detect tenderness and pain, resting tone, contraction strength, and ability to relax. Some women have an “overactive pelvic floor” characterized by generally high resting tone. Others may have increased muscle tension only when attempting to void.

When muscle tension or spasm is detected, behavioral treatment focuses on teaching conscious relaxation of PFM, especially in the context of voiding. The first step is to educate the patient about bladder and pelvic floor anatomy and function. Normal voiding is a coordinated process, in which pelvic floor relaxation precedes and can initiate detrusor contraction and urethral relaxation. Some women habitually void by Valsalva, believing that they need to bear down to push urine out and empty the bladder. This can result in a reflex contraction of the PFMs, impeding urine flow. Patients with dysfunctional voiding need to understand that pushing is not necessary and may be counterproductive. Instead, they can facilitate voiding through volitional PFM relaxation, which will allow the bladder to empty naturally.

PFMT focuses on developing an awareness of muscle tension as distinct from muscle relaxation. Actively contracting the muscles demonstrates the sensations associated with muscle tension and assists patients to discriminate and contrast it with the sensations of relaxation. An active contraction also leads to a more complete subsequent relaxation. BF can also be used to bring muscle tension to a conscious level.

Using PFMT to enhance muscle relaxation in patients with high-tone PFM is referred to as “down training.” Teaching a muscle to relax is often more difficult than teaching it how to contract (up training). Pain patients will often benefit from BF-assisted PFMT, which enables them to coordinate PFM movement with the BF visual signal. Once they are able to feel the muscle release and relax, the patient can begin coordination of muscle relaxation following a contraction.

As with PFME for incontinence, daily exercise involves not only contracting but also relaxing muscles fully between contractions. This is particularly important for patients with voiding dysfunction. To emphasize relaxation, these patients are taught to focus more on the relaxation phase, which is extended with a 1 : 4 ratio or longer as indicated.

Once the patient has learned the sensation of adequate PFM relaxation during exercise sessions, it is important to address voiding habits so that the relaxation skills can be generalized. For many women, voiding is an activity that is rushed because of a busy lifestyle, and they do not take the time needed to allow normal voiding. **With behavioral treatment, patients are encouraged to create a relaxing environment and plan adequate time for voiding.** They are instructed in good voiding technique. Specifically, they are to slow down, take a deep breath, relax their body, relax their PFMs, and wait for the urine to flow. Anecdotally, some women benefit from double voiding, or lingering until another detrusor contraction occurs, leading to more complete emptying. A second void can be facilitated by rising up from the toilet seat slightly, sitting back down, and relaxing the PFMs once more.

Lifestyle Modifications

In addition to the behavioral interventions that improve symptoms through teaching new skills or strategies, there are a number of lifestyle modifications that change a person's habits and/or lifestyle choices to mitigate factors that may contribute to LUTS. Lifestyle modification involves a conscious choice by the individual to change a practice that is under their control and may contribute to LUTS. Lifestyle modifications are sometimes referred to as “self-care practices.” They can be used as a primary intervention in some cases, but usually they are adjunctive. Lifestyle changes include **fluid management, reduction of caffeine and other dietary irritants, addressing constipation, smoking cessation, and weight loss. Although there is much less evidence for lifestyle modifications** (Imamura et al., 2015), **these changes can have a significant impact on overall bladder health and have become integral to conservative management** (Burgio et al., 2013).

Fluid Management

Fluid intake plays a role in the prevention of several urinary system diseases, and adverse effects on the urinary system can result from insufficient hydration.

Modifying the type or volume of fluids, either as a primary or as an adjunctive strategy, is often recommended to optimize outcomes as part of conservative intervention for LUTS. Fluid intake modifications depend on the patients' pattern of intake, which can be assessed by having them complete a 24- to 48-hour diary of intake and output, including voided volumes when possible. Reviewing such a diary can reveal excessive fluid intake, inadequate fluid intake, and diurnal patterns of intake that may be contributing to LUTS.

Excessive Fluid Intake.

Excessive fluid intake **can be a problem when large-volume intake triggers symptoms of urgency, frequency, or incontinence** (Segal et al., 2011). Fluid intake averaging more than 3700 mL/day has been associated with higher voiding frequency and incidence of UI compared with an intake of approximately 2400 mL/day (Miller et al., 2011). In a study of healthy young men, those with excessive fluid intake had not only significantly increased urine volume and frequency but also significantly elevated bladder pressure on ambulatory urodynamics (Schmidt et al., 2004). Some people increase their fluid intake deliberately in an effort to "flush" their kidneys or lose weight. In others it is simply a habit. In in-depth interviews conducted with participants in the Boston Area Community Health (BACH) study (Elstad et al., 2011), women reported the need to increase fluid intake attributing it to popular health messages recommending daily fluid intake and that water was "good for you." Men, on the other hand, tended to describe the function of water in the body was to ward off infection, "flush out the kidneys," or "keep your system cool." **When patients consume an abnormally high volume of fluid (e.g., >2100 mL of output per 24 hours), reducing excess fluids is often an appropriate measure and can be helpful for reducing urgency, frequency, and urgency incontinence**.

Inadequate Fluid Intake.

In practice, it is more common to see inadequate fluid intake, because people with bladder problems often restrict their intake in an effort to control symptoms. In the BACH study interviews (Elstad et al., 2011), men and women across all three racial/ethnic groups reported decreasing fluid intake to manage or cope with urinary symptoms. Studies of community-residing elders with LUTS also report self-care practices including self-imposed restrictions of fluids to prevent urinary urgency, frequency, and incontinence (Brink et al., 1987; Diokno et al., 2004a, 2006; Johnson et al., 2000; Miller et al., 2003; Wyman and Fantl, 1991; Wyman et al., 2009). Working women also report limiting fluid intake as strategies to avoid urinary symptoms (Fitzgerald et al., 2000, 2002; Nygaard et al., 1997).

In some cases, particularly in older adult women, the resulting fluid intake may be inadequate and places them at risk of dehydration. Underhydration may play a role in the development of urinary tract infections and constipation and decrease the functional capacity of the bladder. In a study of 791 female teachers, those who drank less than the volume they desired had more than twice the risk of UTI (Nygaard et al., 1997).

Fluid intake should be regulated to 6 to 8 8-ounce glasses or 30 cc/kg body weight per day with a 1500 mL/day minimum at designated times unless contraindicated by a medical condition. The Institute of Medicine issued a report (2005) **with guidelines for total water intake for healthy people**. **That recommendation for women was 2.7 L per day but was intended to include water consumed through beverages and food.** This food versus fluid component has been a source of confusion for the public and professionals, with a misperception of fluid source as only deriving from beverage intake. In an older adult, who may be limiting fluid intake because of the fear of LUTS and is at risk for dehydration, an oral fluid record should be considered (Palmer et al., 2014).

A useful strategy to encourage increased fluid intake when appropriate is to point out that concentrated urine has a stronger odor than more dilute urine. Patients with incontinence are often sensitive about urinary odor and welcome a suggestion to decrease odor.

Timing of Fluid Intake.

Although overall fluid restriction is not a good strategy, **it can be very helpful to restrict fluids at particular times when toilet access will be limited,** such as before a social outing. Patients using temporary fluid restriction should be encouraged to keep their total daily fluid intake optimized, by making up the missed fluids earlier or later.

Avoiding excessive fluid intake in the evening hours can also be helpful for reducing nocturia (e.g., 3 to 4 hours before bedtime)**. In patients who retain fluid during the day and have nocturia resulting from mobilization of fluid during sleep, behavioral interventions focus on managing daytime accumulation of fluid. Patients are advised to wear support stockings to**

prevent accumulation of edema fluids or to elevate the lower extremities in the late afternoon to mobilize the fluid well before bedtime.

In some patients, a mid- to late afternoon loop diuretic is useful to complete diuresis before bedtime. For patients who are already taking a loop diuretic, nocturia can often be improved by altering the timing of the diuretic (so that most of the effect has occurred before bedtime). Loop diuretics are also known to aggravate incontinence by increasing the rate of bladder filling and producing sudden urges. Such effects can sometimes be avoided by discontinuing the diuretic, changing to a non-loop diuretic, or altering the timing of administration. An example is taking the loop diuretic in the later afternoon or *after* coming home from work so that diuresis can be accomplished during the evening, but before bedtime.

Evidence for Fluid Management.

Although fluid management is widely used in clinical practice, **there is little scientific evidence on fluid intake related to bladder health.** Two small randomized trials suggest a negative effect for increased fluid intake. In one study ($n = 24$), adults with OAB were randomized to either decrease or increase fluids (Hashim and Abrams, 2008). When patients decreased their fluid input by 25%, there was a significant reduction in daytime frequency (23%), urgency (34%), and nocturia (7%). Increasing fluid input by 25% and 50% resulted in a worsening of daytime frequency but had no effect on urgency, nocturia, or urgency incontinence. In a study of women with urodynamically confirmed idiopathic detrusor overactivity ($n = 30$), decreasing fluid intake significantly decreased voiding frequency and urgency incontinent episodes (Swithinbank, Hashim, and Abrams, 2005). However, the Nurses’ Health Study prospectively investigated the association between total fluid intake and incident UI over 4 years in 65,167 women and found no association between fluid intake and UI (including stress, urgency, and mixed UI) (Townsend et al., 2011).

Caffeine Reduction

Caffeine plays a role in symptoms of urgency, frequency, and urgency incontinence partly because it is a diuretic and partly because it is a bladder irritant for many people. The consumption of caffeinated beverages, foods, and medications is easily underestimated. Caffeine is found in many foods and drinks that people consume daily, particularly coffee and tea. Caffeine is consumed regularly by more than 85% of adults in the United States (Mitchell et al., 2014). Approximately 73% of children consume caffeine on a given day, and coffee and energy drinks represent a greater proportion of caffeine intake than soda intake, which has declined (Branum et al., 2014).

Urodynamic studies have shown that caffeine increases detrusor pressure (Creighton and Stanton, 1990) and is a risk factor for detrusor overactivity (Arya et al., 2000; Holroyd-Leduc et al., 2004). Caffeine promotes LUTS via decreased threshold of sensation in the filling phase and increased flow rate and voided volume (Jura et al., 2011; Lohsiriwat et al., 2011). Lohsiriwat et al. (2011) found that caffeine, at a dose of 4.5 mg/kg, caused diuresis and decreased the threshold for bladder sensation in the filling phase, with an increase in flow rate and voided volume. Similarly, daily administration of oral caffeine (150 mg/kg) resulted in detrusor overactivity and increased bladder sensory signaling in the mouse (Kershen et al., 2012).

Caffeine intake has also been associated with LUTS in epidemiologic studies in men (Davis et al., 2013) and women (Gleason et al., 2013; Jura et al., 2011; Townsend et al., 2012). Data from the Nurses' Health Study II reported that 25% of these participants experienced frequent (at least once a week) UI with high caffeine intake (Townsend et al., 2012). The BACH study reported on beverage intake and LUTS in a large cohort (n = 4144) (Maserejian et al., 2013). Women who had increased coffee intake by at least 2 servings/day had 64% higher odds of progression of urgency. Women who had recently increased soda intake, particularly caffeinated diet soda, had higher symptom scores, urgency, and LUTS progression.

In men, greater coffee intake (>2 cups/day vs. none) or total caffeine intake at baseline increased the odds of storage symptom progression (Maserejian et al., 2013). Davis et al. (2013) also found that caffeine consumption (equivalent to approximately 2 cups of coffee daily; 250 mg) was significantly associated with moderate to severe UI in US men.

There is also evidence that reducing caffeine intake can help to reduce episodes of stress and urgency incontinence (Bryant et al., 2002; Gray, 2001; Tomlinson et al., 1999). **Based on the literature, the ICI recommends a reduction in caffeine intake to improve incontinence and related symptoms** (Dumoulin et al., 2017). However, the amount of caffeine reduction necessary to prevent associated LUTS is not known.

Many patients are reluctant, initially, to forgo their caffeinated beverages, but they may be convinced to try it for a short period of time, such as 3 to 5 days, to determine if they are sensitive to caffeine's effects. If they experience relief from their symptoms, they are often more willing to reduce or eliminate caffeine from their diet. To avoid symptoms of caffeine withdrawal, most notably headaches and irritability, it is recommended that caffeine reduction be approached gradually and include mixing caffeinated and decaffeinated beverages incrementally over several weeks.

Other Dietary Irritants

Although data are scarce, there are a number of other substances that are thought to irritate the bladder, including sugar substitutes (aspartame), citrus fruits, highly spiced foods, and tomato products. There are innumerable clinical cases in which these substances appear to be aggravating urgency and incontinence, and reducing them has provided clinical improvement. However, this should not be interpreted to mean that all patients with LUTS should eliminate these foods from their diets. **A diary of food and beverage intake is useful for identifying which substances are in fact irritants for individual patients;** and a trial period of eliminating these substances one at a time can be used to confirm the relationship.

It has also been **suggested that alcohol intake can contribute to urgency, frequency, and incontinence by means of a diuretic effect. However, there is little in the literature to support this hypothesis.** In a study of alcohol consumption and UI among community-dwelling Japanese women (Hirayama and Lee, 2012), increases in risk of UI with alcohol drinking and mean ethanol intake did not reach statistical significance.

A study in men concluded that among other factors, alcohol consumption was an avoidable risk factor for the development of LUTS (Haidinger et al., 2000). Another study in men aged at least 20 years demonstrated that high alcohol consumption was a factor positively associated with an increased risk of moderate and severe LUTS (Seim et al., 2005). Research is needed on the effect of caffeinated alcoholic beverage on LUTS because consumption is widespread among adults in the United States (MacKillop et al., 2012). Acidic liquids and fruit intake are also thought to contribute to UI, but Townsend et al. (2013) found no relation between acidic fruit intake and UI in a large prospective study of women enrolled in the Nurses’ Health Studies.

Bowel Function

Bowel disorders, including chronic constipation (fewer than 3 stools per

week) and straining during defecation, have been linked to LUTS (Cardozo and Robinson, 2002; Carter et al., 2012), and the ICI committee concluded there is "some evidence" to suggest that chronic straining during defecation may be a risk factor for the development of UI (Dumoulin et al., 2017). The proximity of the bladder and urethra to the rectum and their similar nerve innervations make it likely that there are reciprocal effects between them. As early as 1988, Lubowski reported that denervation of the external anal sphincter and PFMs may occur in association with a history of excessive straining on defecation (Lubowski et al., 1988). Many believe that if straining is a lifetime habit, it may have a cumulative effect on pelvic floor and bladder function as well. Further, animal studies and clinical data support bladder-bowel cross-sensitization, or crosstalk between the bowel and bladder (Kaplan et al., 2013).

The Epidemiology of Lower Urinary Tract Symptoms (**EpiLUTS) II** (Coyne et al., 2011) survey (n = 2160) **indicated that OAB is more likely to be reported by men and women with chronic constipation.** In a case-control study of women with LUTS (n = 820) and matched controls (n = 148), constipation and straining during defecation were significantly more common among the women with LUTS, including detrusor overactivity and urgency, than among the controls (Manning et al., 2003). In a prospective observational cohort study of more than 500 women seeking care for LUTS (Cameron et al., 2018), when compared with those without UI, women with UI had higher PROMIS (Patient-Reported Outcomes Measurement Information System) constipation (51.9 vs. 48.4, $P = 0.003$), and diarrhea scores (49.5 vs. 46.2, $P = 0.008$), indicating worse bowel function. The presence of UI was associated with constipation and more severe UI symptoms, regardless of UI subtype, were associated with worse bowel function (fecal incontinence, diarrhea, constipation).

Fecal impaction and constipation have been cited as factors contributing to UI in women, particularly in nursing home populations (Ouslander and Schnelle, 1995b). Fecal impaction can be an irritating factor in OAB or obstruct normal voiding, causing incomplete bladder emptying and overflow incontinence.

Self-care practices that promote bowel regularity are an integral part of any behavioral treatment plan. Initial assessment should include questions about bowel history and bowel habits. When constipation is reported, recommendations include ensuring adequate dietary fiber and fluids to ensure normal stool consistency. Sufficient fluid intake is necessary for fiber supplementation to be effective. Also helpful are regular exercise, external stimulation, and establishment of a regular time for bowel evacuation, preferably after a meal to capitalize on postprandial bowel motility.

Obesity and Weight Reduction

Obesity is the most clearly established risk factor for UI. There is a large amount of epidemiologic and interventional data, including several systematic reviews, demonstrating an association between body mass index (BMI) and UI, as well as for other LUTS, including urgency and frequency (Dallosso et al., 2003; Khullar et al., 2014; Milsom et al., 2017; Subak, et al., 2009; Vaughan et al., 2012). Across a wide range of studies, obese women have approximately double the risk of UI. Further, **reductions in UI have been observed in morbidly obese women who have had dramatic weight loss after bariatric surgery** (Bump et al., 1992; Burgio et al., 2007; Knoepp et al., 2013) **and in women who achieved moderate weight loss through supervised behavioral weight-loss programs** (Bump et al., 1992; Subak et al., 2005, 2009; Wing et al., 2010a,b). Obesity increases intra-abdominal pressure, predisposing to stress UI, whereas metabolic syndrome associated with obesity predisposes to urgency UI.

Knoepp et al. (2013) reported on the resolution and incidence of UI in women undergoing bariatric surgery by examining national claims data for 3765 cases with 3 years of follow-up claims data. After surgery, 62.4% of patients (83/133) diagnosed with UI before their surgery no longer had a coding diagnosis of UI. In contrast, only 42.1% (56/133) of those in a non-bariatric surgery cohort lost their coding diagnosis of UI (P = 0.0009). Incidence of new UI did not differ significantly between the groups, however.

Even moderate weight loss has been shown to improve bladder symptoms in overweight women. In fact, loss of 5% to 10% of body weight, sustained over a 12-month period, can decrease incontinence episodes as much as 70% (Bump et al., 1992; Subak et al., 2005; Wing et al., 2010a,b). The most definitive of the studies is a randomized trial comparing the effects of an intensive 6-month, group-administered, weight-loss program (including diet, exercise, and behavior modification) to a structured education control program (Subak et al., 2009). Both groups also received a booklet describing a step-by-step self-administered behavioral program to reduce incontinence. After a mean weight loss of 8.0%, the weight loss group reported a significantly greater reduction in incontinence episodes compared with the control group with a mean weight loss of 1.6% (mean = 47% vs. 28%). Thus weight loss can be a useful component of a behavioral program for incontinence in overweight women.

Based on this evidence, **more clinicians should recommend weight loss as a component of lifestyle interventions for UI in overweight women** (Vissers et al., 2014). Given that BMI is a modifiable risk factor, it is plausible that UI may be prevented if women maintain their weight within suggested guidelines.

Adherence to Conservative Treatment

It is widely accepted that the effectiveness of conservative behavioral treatments relies on the active participation of an involved and motivated patient (Dumoulin et al., 2015a). In fact, most behavioral interventions can be conceptualized as self-management. Therefore the greatest challenge for the clinician becomes how to motivate patients to be actively involved in their care, to follow their daily program consistently, and to persist for long enough to experience meaningful change in their symptoms. Progress in behavioral programs is typically gradual, which makes compliance even more difficult for patients who expect immediate results. **Clinicians can support patient adherence by communicating realistic expectations, making it clear that it may take weeks to months for symptom improvement, and it may be irregular, with "good" days and "bad" days.** Clinicians can provide support by scheduling follow-up appointments to maintain accountability, track and reinforce progress, identify and address barriers, adjust the daily regimen, encourage persistence, and let patients know that they are not alone.

Measurement of adherence to behavioral protocols has often been overlooked in research (Dumoulin et al., 2015b). **Few studies provide information about how adherent patients were with PFME, behavioral strategies, voiding schedules, or other components of behavioral treatment** (Bø and Talseth, 1996; Borello-France et al., 2010; Dumoulin et al., 2015b; Fine et al., 2007; Mørkved et al., 2013), **and the literature is sparse on methods to identify barriers and improve adherence** (Alewijnse et al., 2003; Bø et al., 2005; Borello-France et al., 2010, 2013; Dumoulin et al., 2015b).

Borello-France et al. (2013) reported on adherence to PFME and bladder control strategies as a secondary analysis of a multi-site RCT comparing three interventions for stress-predominant UI: intravaginal continence pessary versus multi-component behavioral therapy (including PFMT and bladder control strategies) versus pessary and behavioral therapy combined (Richter et al., 2007). The authors concluded that adherence to PFME and bladder control strategies, when implemented by trained interventionists, can be high and sustained over time.

The most common barriers to adherence were trouble remembering to exercise and difficulty finding time. To help patients overcome these particular barriers, clinicians can use various forms of reminders (e.g., timers), provide exercise aids, link daily exercises to environmental cues, and integrate exercises into the patient's everyday activities.

Other reported determinants of adherence to PFMT include positive intentions to adhere, self-efficacy expectations, attitudes about the exercises and its benefits, perceptions of social pressure and enthusiasm of the therapist (Alewijnse et al., 2003; Dumoulin et al., 2015b). Patients and clinicians agree that patient-related factors are the most important adherence barriers (Frawley et al., 2015). A review of qualitative studies (*n* = 13) identified six “modifiers” of adherence: knowledge; physical skill; feelings about PFMT; cognitive analysis, planning, and attention; prioritization; and services provision. Women described difficulties in each of these areas when adopting and maintaining a program of PFME (McClurg et al., 2015). Given the multi-faceted nature of adherence and differences among patients’ personal circumstances, it is recommended that clinicians assess adherence, during and at the end of therapy, and employ patient-focused strategies to enable adherence and optimize the benefits of intervention (Dumoulin et al., 2015a).

Although most clinicians agree that adherence to a maintenance protocol is necessary for long-term effectiveness, **there is little work on long-term adherence or the durability of the effects of behavioral treatments.** Long-term studies have shown that women following a PFMT program tend to decrease their adherence over time (Fine et al., 2007). Bø and Hilde (2013) reported that long-term adherence to PFMT varied between 10% and 70%. Work on determinants of long-term adherence has identified positive adherence intentions and self-efficacy expectations (Alewijnse et al., 2003). The few studies of long-term outcomes are inconsistent, but promising, in that many patients are able to sustain improvements in bladder control over time (Bø and Talseth, 1996; Cammu and Van Nylen, 1995; Weinberger et al., 1999). There is clearly a need for more studies of long-term outcomes to understand the reasons for regression and to learn how the effects of treatment can be maintained over a lifetime.

Prevention of Urinary Incontinence

The noninvasive nature of conservative interventions allows for their use as preventive strategies. Primary prevention of UI using behavioral interventions, including PFMT, behavioral training, or lifestyle changes (weight loss, fluid moderation, diet modification), has been investigated in three at-risk populations: older women, childbearing women, and men undergoing prostatectomy (Dumoulin et al., 2017; Newman et al., 2017; Sievert et al., 2012).

Older Women

Age is perhaps the most established risk factor for UI in men and women; however, little work has been done to study approaches to preventing UI in this population. The **first prevention study** was an RCT comparing a group behavior modification program to no intervention in continent, postmenopausal women, 55 years and older, to determine whether the behavioral intervention could prevent UI, increase PFM strength, and decrease voiding frequency (Diokno et al., 2004a,b). **At 12 months, the treatment group had statistically significantly better outcomes than the control group** in continence status, PFM strength (pressure score and displacement score), improved voiding frequency, and intervoid interval.

Later, a smaller study was conducted in 43 women, 65 years and older, residing in an independent-living facility to determine the feasibility of a 6-week pelvic fitness and educational program to control UI and OAB (Dugan et al., 2013). Statistically significant improvements in bladder symptoms were found after 6 weeks in the treatment group, based on visual analog scale scores for symptom bothersomeness, symptoms distress (Urogenital Distress Inventory, short form), and impact on QoL (Incontinence Impact Questionnaire, short form).

Two methods for delivering bladder health information including behavioral skills, a 2-hour bladder health class and a 20-minute video, were compared in a randomized trial with 647 older women (55 years or older) who were essentially continent (no UI or only minimal leakage) (Sampselle et al., 2017). Neither group showed significant increases in incontinence or urgency after 12 and 24 months, indicating lack of symptom progression. Further, outcomes did not differ significantly between groups, indicating that the interventions were comparable.

Childbearing Women

Pregnancy and childbirth are established risk factors for UI in women. For this reason, most prenatal classes include teaching about the role of the pelvic floor and PFM exercises. There is also a **growing body of evidence for the preventive value of formal PFMT.** Research with primiparous women has shown that intensive antenatal PFMT, including one-on-one instruction to ensure proper muscle control and continued supervision of training, can prevent the development of UI during pregnancy (35 to 36 weeks' gestation) and short-term postpartum (6 weeks to 6 months) (Boyle et al., 2012, 2014; Dumoulin et al., 2017; Mørkved and Bø, 2013; Pelaez et al., 2014). A recent Cochrane review examined the evidence for PFMT based on 38 trials involving 9892 women from 20 countries. Similarly, the authors concluded that in continent pregnant women, performing antenatal PFMT may decrease the risk of UI in late pregnancy and in the mid-postnatal period (>3 to 6 months postpartum) (Woodley et al., 2017).

Less clear is the impact of PFMT on preventing UI long term and in multiparous women. Based on research, the ICI committee (Dumoulin et al., 2017) recommends (a) an intervention comprising a daily home PFMT and weekly health professional-led exercise classes for 12 weeks, starting at 16 to 24 weeks' gestation for pregnant women, and (b) an individually taught strengthening PFMT program that incorporates adherence strategies for postpartum women who have had a forceps delivery or a vaginal delivery of a large baby (4000 g or more). **The ICI also recommended education to older women to prevent UI should be provided** (Newman et al., 2017).

Men Undergoing Prostatectomy

Postoperative UI is almost universal immediately after prostatectomy. Although continence status usually improves in the ensuing weeks and months, the literature is mixed with regard to the effects of various approaches to behavioral treatment of post-prostatectomy UI (Anderson et al., 2015). **There is some evidence that it is possible to speed the recovery of continence using behavioral interventions such as PFMT. One approach is to teach men how to control their PFM before surgery,** so they will have the opportunity to practice using their muscles in advance of needing to use them more actively after surgery. In one trial, a single session of BF-assisted behavioral training reduced the duration of UI, as well as severity of symptoms in the 6 months after radical prostatectomy (Burgio et al., 2006).

Another approach is to initiate PFMT immediately after catheter removal or early in the recovery period. Results of this approach are inconsistent but generally show benefit for the training at least in the first 3 months (Filocamo et al., 2005). **Trials that have combined preoperative and early postoperative training also indicate that severity of post-prostatectomy UI can be reduced with PFMT, in the short term (3 months)** and in some studies up to 12 months (Hirschhorn et al., 2014). According to Dumoulin et al. (2017), whether PFMT should be delivered in the form of hands-on therapy or verbal instruction and support remains unclear.

Urology practices have begun to include various levels of PFMT for men undergoing RP; however, translation from research to practice has not been optimum: most men undergoing RP do not receive instruction on PFMT. Some clinicians take the approach of watchful waiting and reserve treatment for men with persistent UI. However, even transient UI can be distressing for men recovery from RP, and hastening the return of bladder control may be important to their activity level, social life, or general well-being.

Future of Lower Urinary Tract Symptom Prevention and Bladder Health Promotion Research

Research on prevention of UI and other LUTS has been an area of growing emphasis. For many years, the ICI has examined various approaches to education-based interventions to increase public awareness and promote bladder health on a population level (Newman et al., 2017). In addition, they have examined a number of delivery models for using more behavioral skill-based approaches to prevention of UI in at-risk populations, such as older adults, childbearing women, and men undergoing prostatectomy.

In 2010 a multidisciplinary panel of experts convened to discuss the importance of a healthy bladder on overall health. They published a consensus statement to raise awareness and encourage stakeholders to pursue primary prevention strategies aimed at providing public education to promote optimal bladder health and reduce the personal, societal, and economic impact of bladder conditions (Lukacz et al., 2011). In addition, they proposed clinical directives based on research to improve and maintain bladder health.

In 2015 the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) formed the Prevention of Lower Urinary Tract Symptoms (PLUS) Research Consortium, a 7-site research network devoted to developing the concept of bladder health and other foundational work to inform future policy and initiatives related to promoting bladder health and preventing LUTS in women and girls across the life course (Bavendam et al., 2016; Harlow et al., 2018).

Vaginal and Urethral Mechanical Devices for Incontinence

Mechanical devices are of two main types, those that are placed in the vagina to support the bladder neck and urethra, and those that are placed in the urethra or at its opening to block the passage of urine. Mechanical devices are most commonly used for stress UI, but they have also been used for urgency and mixed incontinence. There is no device that is used externally over the meatus or inserted in the urethra currently available in the United States. **A 2011 Cochrane review** (Lipp et al., 2011) **noted there was not enough evidence to recommend any specific type of device or to determine whether mechanical devices are better than other forms of treatment.** The ideal mechanical device is one that can adequately control urine leakage, is easy to apply or insert, has few adverse effects, and is of low cost. The following is a short review of devices currently in use.

Intravaginal Devices

Women who leak urine during physical activities may benefit from a mechanical device that provides pelvic support. When pelvic support tissues are weak, the urethra may drop to a position where increased abdominal pressure cannot be transmitted to the urethra assisting with urethral closure. Intravaginal devices aim to restore the position of the upper urethra to above the level of the pelvic floor where intra-abdominal pressure can improve its closure. This can be accomplished using an (in)continence pessary.

A vaginal pessary is one of the oldest medical devices and has been used for centuries as a conservative treatment of POP (Deng, 2018; Shah et al., 2006) and, more recently, for SUI (Nygaard, 1995). The guidelines of the Dutch College of General Practitioners recommend offering women with stress UI a choice between PFMT and a pessary as initial treatment (Daman-Van Beek et al., 2016).

Continence pessaries are placed transvaginally and are designed to prevent urine loss by stabilizing and supporting the urethra and bladder neck, increase urethra length, and provide gentle compression of the urethra against the pubic bone during increases in intra-abdominal pressure. This structural arrangement can reduce and often prevent stress-related incontinence. As seen in Fig. 121.14, the knob of an (in)continence ring pessary is placed against the urethrovesical junction. From this position, the pessary supports the urethrovesical junction in the same way a vaginal sling implanted surgically would (Komesu et al., 2008). In addition to its use in women with stress UI, some women who have urinary urgency and frequency because of pressure from POP may also benefit from the support of a continence pessary.

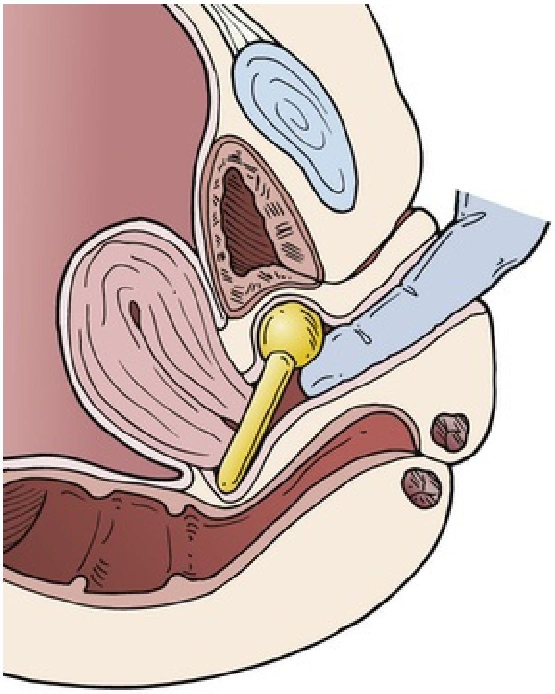

FIG. 121.14 Incontinence ring with support and knob resting against the urethrovesical junction.

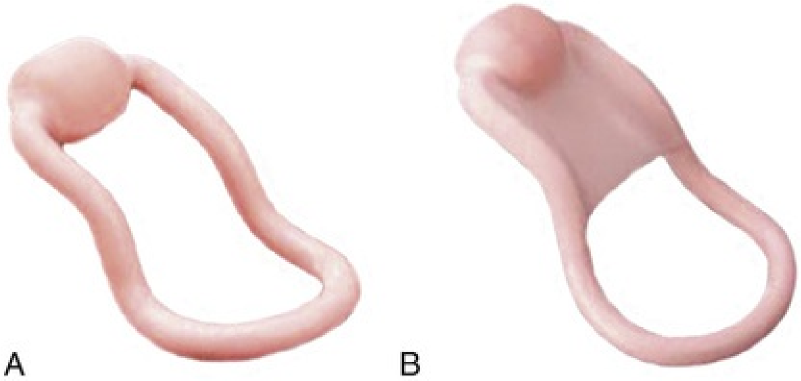
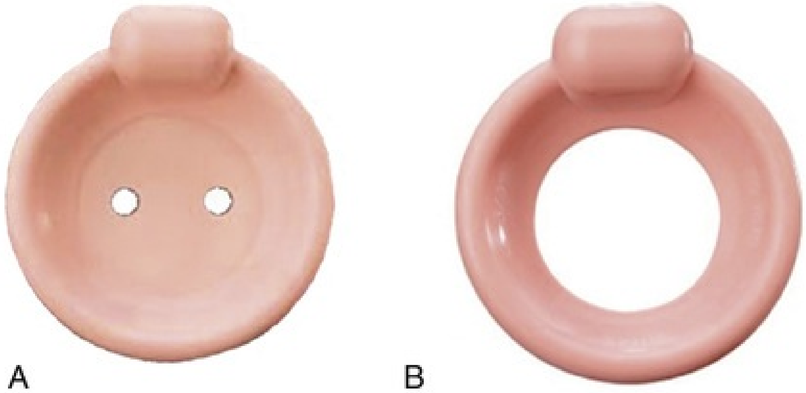
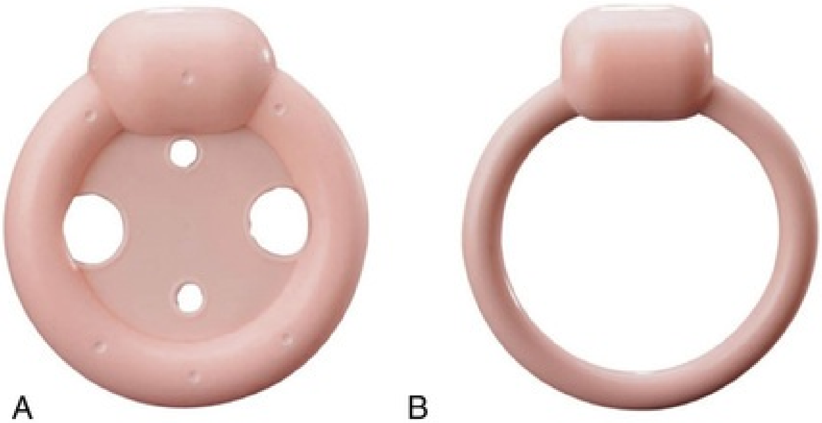
Pessaries are made of an inert plastic or silicone material to prevent odors and absorption of vaginal secretions. Some have been designed to specifically treat stress UI (eFigs. 121.15 to 121.17). There are very few contraindications to pessary use, but a pessary should not be placed in patients with evidence of an active pelvic or vaginal infection, severe ulceration, or allergy to silicone or latex, or in patients who are likely to be noncompliant with maintenance care and follow-up appointments (Deng, 2018). Difficulty with self-removal and insertion may limit more widespread use of currently available pessaries.



EFIG. 121.15 Incontinence hodge pessary (A) without and (B) with support.



EFIG. 121.16 Incontinence dish pessary (A) without and (B) with support.



EFIG. 121.17 Incontinence ring pessary (A) without and (B) with support.

Common side effects include vaginal discharge and odor. Serious complications from pessaries are rare; however, vesicovaginal fistula, rectovaginal fistula, erosion, and subsequent impaction have been reported (Arias et al., 2008; Penrose et al., 2014). The more severe complications were reported after long-term (6–10 years) use of pessaries in patients with prolapse. They included bleeding, severe vaginal discharge, pain, and constipation; 23% of women had more than one type of complication and most had more than one episode (Sarma et al., 2009). A continence pessary can be worn continuously or intermittently during exercise or physical activity.

Research on pessary use for incontinence is limited. Stress and mixed UI improved with a pessary in approximately 50% of women in two trials (Donnelly et al., 2004; Richter et al., 2010). A multi-site randomized trial of a continence pessary compared with behavioral therapy was conducted by the NICHD Pelvic Floor Disorders Network (Richter et al., 2010). The Ambulatory Treatments for Leakage Associated with Stress Incontinence (ATLAS) trial randomized 446 women with stress predominant incontinence to intravaginal pessary, behavioral therapy, or combined treatment. At 3 months, 40% of the pessary group and 49% of the behavioral group rated themselves as “much better” or “very much better,” but these outcomes were not statistically different. Significantly ($P = 0.006$), more women in the behavioral group than in the pessary group reported having no bothersome incontinence symptoms (49% vs. 33%) and treatment satisfaction (75% vs. 63%). The combined group had a 44% success rate, which was significantly better than the pessary group but not the behavioral group. At 12 months, patient satisfaction remained above 50% for all treatment groups, but group differences were not sustained on any measure.

Sze and Hobbs (2014) performed a comparative retrospective parallel cohort study of women whose OAB was treated with ring pessary or multicomponent behavioral therapy (BT while using PFME to suppress urinary urgency as needed) over a 42-month period. Ring pessary and behavioral therapy had similar cure rates (29 out of 150 [19%] vs. 46 out of 231 [20%], respectively).

There are other intravaginal devices available to control incontinence, with different mechanism of action, materials, and designs than a pessary (Deng, 2018); these include the Uresta and the Impressa.

The Uresta is a bell-shaped pessary (eFig. 121.18) with a handle at its base for easy insertion and removal. Its narrow tip allows for easy insertion into the vagina, like a tampon, and it positions itself so that the wide base provides support to the urethra (see Fig. 121.19). A complete Uresta set includes three sizes (size 3, 4, and 5) that can be fitted by a health care provider or by the patient. Farrell et al. (2007) tested this intravaginal device in 32 women. Incontinence episodes decreased by 4 per week (based on 7-day diary) (P = 0.028) and pad weights by 11 g (P = 0.006). No complications were reported. At 2 weeks, 66% of women were satisfied with the pessary. After 12 months, 50% of subjects continued pessary use with statistically significant differences in number of leakage episodes, pad weight, symptom severity, and impact on QoL.

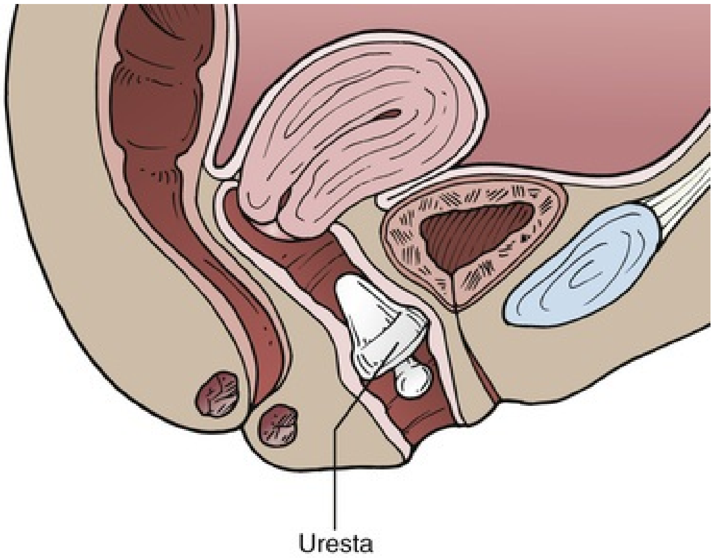


FIG. 121.19 Uresta in place.

EFIG. 121.18 Uresta kit.

Impressa is a disposable single-use tampon-like device that has a core, cover, and applicator (see Fig. 121.20). The core is made of medical-grade silicone, composed of flexible anchor and support poles made of resin. The Impressa is designed to prevent the device from moving within the vagina and to produce sub-urethral tension-free support whenever pressure is transferred from the abdominal cavity to the pelvic floor (eFig. 121.21). The cover around the core is made of soft, biocompatible, nylon mesh that stretches between the arms of the support poles to act as a tension-free sling without obstructing urinary flow or vaginal secretions. The core and cover are preassembled within a smooth, small-diameter plastic applicator similar to those used for tampons, allowing for insertion directly into the vagina and a string for removal. It is nonabsorbent, and it is not necessary to remove it before urination or defecation but should be removed during menstruation and sexual intercourse. In an open-label, controlled, two-center study, 60 women were recruited to test the device for 28 days. The primary end point was the percentage of women who achieved a more than 70% reduction in pad weight gain from the control period to the last 14 days of Impressa device usage. All women had severe stress UI based on pre-study urodynamic study. Eighty-five percent of participants achieved a more than 70% reduction in pad weight gain. Mean pad weight in grams decreased from 17 g/8 hours to 2 g/8 hours. This is a mean percent reduction of 86%. All women reported feeling urine leakage during the control period, whereas only

8% felt UI at study end. Urinary flow rates and postvoid residual volumes were not significantly changed. Postvoid residual volumes were 14.5 mL pre-study compared with 17 mL during device usage. A high degree of satisfaction was reported. Ninety-two percent of the women reported a QoL improvement of 10%, 88% reported a QoL improvement of 50%, and 70% of the participants reported 90% improvement (Ziv et al., 2008, 2009). There were 27 cases of vaginal discomfort, 15 cases of vaginal pain, 14 cases of vaginal spotting (mild), and 1 case of candidiasis. There were no vaginal excoriations, sores, ulcers, scratches, or any signs of inflammation on vaginal exam (Ziv et al., 2008).

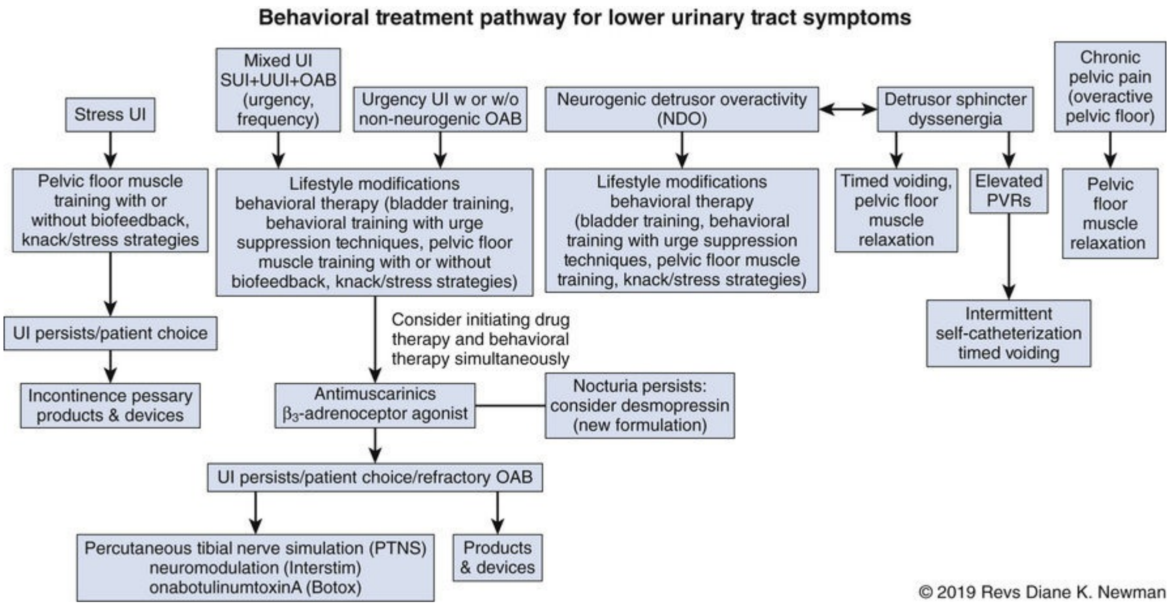
Models of Delivery

Despite the evidence for the effectiveness of behavioral treatments for UI and other LUTS, and guidelines recommending them as first-line therapies, these conservative interventions are not well integrated into clinical practice or widely accessible in many areas. One limitation has been the availability of qualified providers.

One successful model that has emerged in urologic practice is the integration of advanced practice providers (APPs), including continence nurse practitioners and physician assistants. Historically, APPs have embraced behavioral treatments as a specialty practice for nonsurgical treatment of a wide range of lower urinary tract conditions. An algorithm for a behavioral treatment pathway can be found in eFig. 121.22. Urology lends itself to a multidisciplinary model of a continence and pelvic health service that provides comprehensive surgical and medical care. These centers usually offer the combined knowledge of a multidisciplinary group of experts in the field of UI, voiding, and pelvic floor dysfunction. Changes in reimbursement for nonsurgical treatments such as BF-assisted PFMT, E-stim, and posterior tibial nerve stimulation have allowed urologists to consider the expansion of current treatments (pharmacologic and surgical) to alternative multi-faceted behavioral treatment programs.



Behavioral treatment pathway for lower urinary tract symptoms
Stress UI
Mixed UI SUI+UUI+OAB (urgency, frequency)
Urgency UI w or w/o non-neurogenic OAB
Neurogenic detrusor overactivity (NDO)
Detrusor sphincter dyssenergia
Chronic pelvic pain (overactive pelvic floor)
Pelvic floor muscle training with or without biofeedback, knack/stress strategies
Lifestyle modifications behavioral therapy (bladder training, behavioral training with urge suppression techniques, pelvic floor muscle training with or without biofeedback, knack/stress strategies)
Lifestyle modifications behavioral therapy (bladder training, behavioral training with urge suppression techniques, pelvic floor muscle training, knack/stress strategies)
Timed voiding, pelvic floor muscle relaxation
Elevated PVRs
Pelvic floor muscle relaxation
Intermittent self-catheterization timed voiding
UI persists/patient choice
Consider initiating drug therapy and behavioral therapy simultaneously
Incontinence pessary products & devices
Antimuscarinics β_3-adrenoceptor agonist
Nocturia persists: consider desmopressin (new formulation)
UI persists/patient choice/refractory OAB
Percutaneous tibial nerve simulation (PTNS) neuromodulation (Interstim) onabotulinumtoxinA (Botox)
Products & devices

Another approach to improving access to behavioral intervention is use of group delivery models (Newman et al., 2017). PFMT has long been included as a component of prenatal education classes and fitness classes to promote pelvic health during pregnancy and the postpartum period (Bø et al., 2011; Hilde et al., 2014; Pelaez et al., 2014). PFMT has also been integrated into general fitness programs, as well as specific pelvic health classes (Alves et al., 2015; Bø et al., 1990; de Oliveira et al., 2009; Dugan et al., 2013; Felicissimo et al., 2010; Hill et al., 2007; Janssen et al., 2001; Kim et al., 2011; Lamb et al., 2009; Pereira et al., 2011) to treat symptomatic women. These programs generally focus on strengthening PFMs and therefore require multiple sessions across several weeks. Other group programs are delivered in a classroom or community setting and use more of a health class format (Diokno et al., 2004a,b, 2018; Sampselle et al., 2017; Tak et al., 2012; Tannenbaum et al., 2013). These classes take a broader behavioral approach with multiple components, including education about bladder anatomy and function, voiding habits, toileting techniques, and/or behavioral strategies for bladder control. Such bladder health classes have been shown to be effective for preventing symptoms in older populations (Diokno et al., 2004a,b; Sampselle et al., 2017), and as well as for reducing existing symptoms (Diokno et al., 2010, 2018; McFall et al., 2000; Tannenbaum et al., 2013).

Diokno et al. (2018) conducted a multisite RCT of community-dwelling adult women (mean [SD] age, 64 [7] years) with UI who were randomized to either a one-time group-administered behavioral treatment (GBT) that included a 2-hour bladder health class supported by a PFME audio CD (n = 232) or a control no-treatment group who received no treatment (n = 231). Both groups were followed for 12 months. Primary outcome was a change in International Consultation on Incontinence Questionnaire-Short Form (ICIQ-SF) score. In the intent-to-treat analysis, the ICIQ-SF score for the GBT was consistently lower than control across all time points (3, 6, 9, 12 months) but did not achieve the projected 3-point difference. The authors note that a one-time GBT is modestly effective and cost effective for reducing UI frequency, severity, and bother and improving QoL in older adult women.

These less-intensive programs may not be as effective as more individually supervised therapies recommended by guidelines. However, they are essentially risk free, can be cost effective, and can be implemented by health care professionals in a variety of medical or nonmedical settings. Thus they have the potential to reach a broader population of men and women, including those with mild or preclinical symptoms, conveying basic information about their bladder health and techniques that can treat, prevent, or delay onset of symptoms, as well as the availability of other more traditional treatment approaches should they wish to access the health care system.

Key Points

- Conservative behavioral treatments are a group of interventions that improve urinary incontinence and other LUTS by changing patients' behavior or environment or by teaching new skills.
- There is strong evidence that conservative interventions are effective first-line treatments for patients with UI and other LUTS.
- The effectiveness of conservative treatments relies on the active participation of an involved and motivated patient.
- Intensive behavioral interventions that involve an experienced clinician have been shown to be more effective.

Electrical Stimulation and Neuromodulation in Storage and Emptying Failure

John P.F.A. Heesakkers MD, PhD, Bertil Blok MD, PhD

History of Electrical Stimulation

Influencing the behavior of the lower urinary tract through electrical stimulation of the innervation system can be regarded as successful and multi-potent. However, the idea of achieving a specific response in human organs by electrical stimulation of the nervous system is conceptually logical, of long standing, and by no means confined to urology.

As early as the year 46, Scribonius Largus already described how the torpedo fish, the ray, and the eel could be used for the treatment of headaches and gout in his *Compositiones medicae.* As quoted by Martellucci (2015), Scribonius Largus stated that by direct application of electrical torpedo fish to the human body or by placing painful extremities into a pool of water containing torpedo fish, the resulting electrical shocks stunned the nervous system, allowing an immediate and residual numbness in the extremity (*De compositione medicamentorum liber*. Cratandrus, Basileae 1529; digital edition by the University and State Library Düsseldorf):

> *For any sort of podagra (foot gout), when the pain comes on, it is good to put a living black torpedo-fish under his feet standing on a beach, not dry but one on which the sea washes, until he feels that his whole foot and shank are numb up to the knees. This will both relieve the current pain and alleviate future recurrences.*

Because this method was almost certainly a difficult one to apply, it was not until the invention of the battery in the 18th century that additional medical applications for the use of electricity were developed. Further advances in the field of transistors in the 1950s made it possible to use pacemaker implants in humans for the first time. After it had been proven in the field of cardiology that these implants could successfully stimulate the heart, the use of the technique quickly spread to urology.

In initial experience, these attempts at stimulation were largely muscle based. The most logical idea was to use electric current to stimulate the contraction of the bladder or the sphincter as a treatment for, respectively, bladder contractility and stress incontinence. Caldwell et al. described in 1965 the first use of a sphincter stimulator in an attempt to contract the urethral sphincter. A year earlier, Bradley had tried to produce contraction of the detrusor via direct bladder stimulation. A decade later, Nashold et al. sought in 1972 to induce urination through the electrical stimulation of the sacral cores in the conus medullaris of the spinal cord. This was followed by Jonas et al. (1976), who likewise attempted to trigger micturition with different kinds of surface, deep, and cuff electrodes. However, this proved difficult to achieve during experiments with dogs, because the bladder and the urethral sphincter were activated simultaneously. It was only after this pioneering work on animals that tests were later carried out on neurologic patients. This patient population was chosen because their innervation system was hampered and because the efficient direct stimulation of an organ by electricity was painful in people with a properly functioning innervation system. This was not the case in patients with paraplegia or spina bifida. Unfortunately, these early human tests were not a huge success. Not only was the direct application of the electric stimulation to an organ painful, but also it was relatively ineffective. The stimulation only had an effect in the immediate vicinity of its application. It was eventually discovered that better results could be achieved by indirect stimulation of the end organ via its afferent nerves. This required the use of less current and enabled the entirety of the end organ to be treated. This was the start of the era of practical clinical neurostimulation.

One of the most spectacular applications of neurostimulation in urology was introduced by the neuroscientist Giles Brindley (Brindley and Craggs, 1978). Brindley's sacral anterior root stimulator (SARS) provided stimulation, as the name implies, to the anterior sacral roots responsible for the contraction of the bladder and therefore voiding, defecation, and penile erection. Because anterior stimulation is not able to reduce detrusor overactivity (DO), the SARS was later combined with a sacral dorsal rhizotomy of the same roots. During the last 25 years this combination of rhizotomy and electrical stimulation has resulted in a significant improvement in the quality of life (QoL) for many paraplegic patients by enhancing the functioning of their organs. In addition to Brindley, Sauerwein et al. (1990) in Germany and Sarrias et al. in Spain have also made major contributions to the development and use of this technique.

Around 1985 the emergence of the sacral neuromodulation (SNM), or sacral nerve stimulation (SNS), occurred. The literature is unclear regarding who should claim credit for this discovery, but it gradually became apparent that electric stimulation of the sacral roots could be used to lead not to an increase but to a decrease in bladder activity. This represented a significant breakthrough for the treatment of an overactive bladder (OAB). Up to this point in time, there had been no really effective method for combating this debilitating disorder. Emil Tanagho and Rick Schmidt were the pioneers of SNM, which was successfully introduced into urologic practice worldwide (Bazeed et al., 1982; Hohenfellner et al., 1992; Lue et al., 1985; Thüroff et al., 1982).

It was only with the advent of functional magnetic resonance imaging (fMRI) studies that it became clear that the value of this technique was based on an indirect approach. The sacral roots contain efferent and afferent nerve fibers. The application of an electrical current stimulates the afferent fibers that can influence the relevant areas in the central nervous system (CNS). The stimulus is then conducted by the efferent nerve fibers to the relevant pelvic organs. Because this process does not involve the direct stimulation of the organ but indirectly influences the entire micturition and urine storage system, the procedure is known as neuromodulation. American as well as European pioneers of nerve stimulation and nerve modulation learned the basic techniques of SNM from Emil Tanagho, and theory was successfully put in practice (Van Kerrebroeck et al., 2007).

Around the turn of the 21st century, another new technique made its appearance: percutaneous tibial nerve stimulation (PTNS). For thousands of years Chinese acupuncturists have been activating the acupuncture stimulation point SP6 in the ankle as a treatment for bladder disorders, including OAB. In 1983 McGuire was the first physician who tried to influence the bladder through neuromodulation via the tibialis posterior nerve, situated at the same location as SP6. After this anecdotal use, PTNS spread widely in the years after 2000. This new type of neuromodulation was technically simpler and cheaper than sacral neuromodulation. Because there was no need for an implant and because the stimulation was discontinuous, it was possible to demonstrate the net effect of PTNS in a convincing manner (Peters et al., 2010). New clinical attempts and developments now focus on other sites to stimulate or modulate the lower urinary tract. Examples of these are dorsal genital nerve (DGN) stimulation, pudendal nerve stimulation, intravaginal stimulation, and transcutaneous tibial nerve stimulation (TTNS) by means of a patch. Also, technical developments such as small, chargeable devices are being developed and put into clinical practice. The future will tell which of these developments can stand the test of time.

Neurophysiology Relevant to Electrical Stimulation for Storage and Voiding Disorders

Electrical stimulation for treatment of functional urinary bladder disorders works presumably via modulation of nerves and central neural pathways. It is not known exactly how this electrical therapy works successfully in bladder disorders. Most theories on the working mechanism are focused on the modulation of the central components of the micturition pathways and do not discuss the potential involvement of other brain areas. Some basic knowledge of the main central pathways involved will be summarized.

Failure to urine storage results from either bladder or bladder outlet abnormalities or a combination of both. Such bladder abnormalities include involuntary detrusor contractions, low bladder wall compliance, and altered bladder sensation. Outlet abnormalities include decreased outlet resistance, which may be continuous or intermittent.

Failure to empty the bladder can also occur because of either bladder or outlet abnormalities or a combination of both. Relevant bladder abnormalities include a hypocontractile and/or hyposensitive bladder; outlet abnormalities causing ineffective bladder emptying include anatomic obstruction, such as prostate enlargement and urethral stricture, and urethral sphincter dysfunction or dyssynergia. Electrical stimulation does not restore detrusor or sphincter muscle volume and cannot correct an anatomic abnormality such as urethral stricture or low compliance resulting from fibrosis.

The control of normal urinary continence and urine storage depends on a synergic action between the urinary bladder and the outlet of the bladder of which the external urethral sphincter (EUS) is the most relevant structure. The bladder is relaxed and the EUS continuously contracted involuntarily during the storage or filling phase. When micturition is necessary and socially acceptable, the EUS relaxes first, which is followed 1 to 2 seconds later by a contraction of the detrusor muscle. This antagonistic action between the bladder and its sphincter is controlled by separated descending pathways from the caudal brainstem. Normal voiding is not possible without adequate relaxation of the EUS.

An understanding of the role of the brain and its control of the urinary bladder and urethral sphincter can be facilitated by identifying nuclei and axonal tracts in the caudal brainstem and spinal cord, which are part of the micturition and the continence reflex, and nuclei and axonal pathways, located in the forebrain and mesencephalon, which modulate these micturition and continence reflex areas and their tracts.

The central afferent components of the micturition reflex consist of sacral spinal interneurons and their ascending sensory pathway to the periaqueductal gray (PAG) and the pontine micturition center (PMC) in the caudal brainstem, and the PMC and its descending motor pathway to the preganglionic parasympathetic motoneurons in the sacral cord (Fig. 122.1). The afferent thin, myelinated Aδ nerves from the urothelium, suburothelium, and detrusor muscle in the bladder wall convey bladder filling information via the pelvic and hypogastric nerves to the lumbosacral spinal cord. The afferent information from the bladder neck and urethra is conveyed via the pudendal and hypogastric nerves to the lumbosacral spinal cord (Blok, 2002; De Groat et al., 2015). These lower urinary tract afferents terminate on interneurons in the lateral aspect of the dorsal horn and in the intermediate zone of the lumbosacral cord. Most of the interneurons make intraspinal connections for proprioception, but other spinal interneurons send ascending fiber tracts to specific areas in the pons and midbrain. Some of these interneurons are involved in conveying information related to bladder filling. Other lumbosacral interneurons relay information to forebrain structures, including the thalamus and the hypothalamus (Giesler et al., 1981; Katter et al., 1991). The spinothalamic and spinohypothalamic tracts are thought not to play a specific role in the basic micturition reflex but are involved in sensory processes such as sensation of urogenital pain, temperature, touch, and conscious awareness of bladder filling and voiding. The sensory cortex is constantly informed about the fullness of the urinary bladder via the spinothalamic tract (Chandler et al., 1992). In patients with OAB there is an overawareness of bladder filling, which can be suppressed by conservative or invasive therapy, such as pelvic floor physiotherapy, medication, or electrical stimulation. In patients with complete spinal cord injury (SCI) it is possible that the brain receives bladder fullness information via the vagal nerve (Krhut et al., 2017).

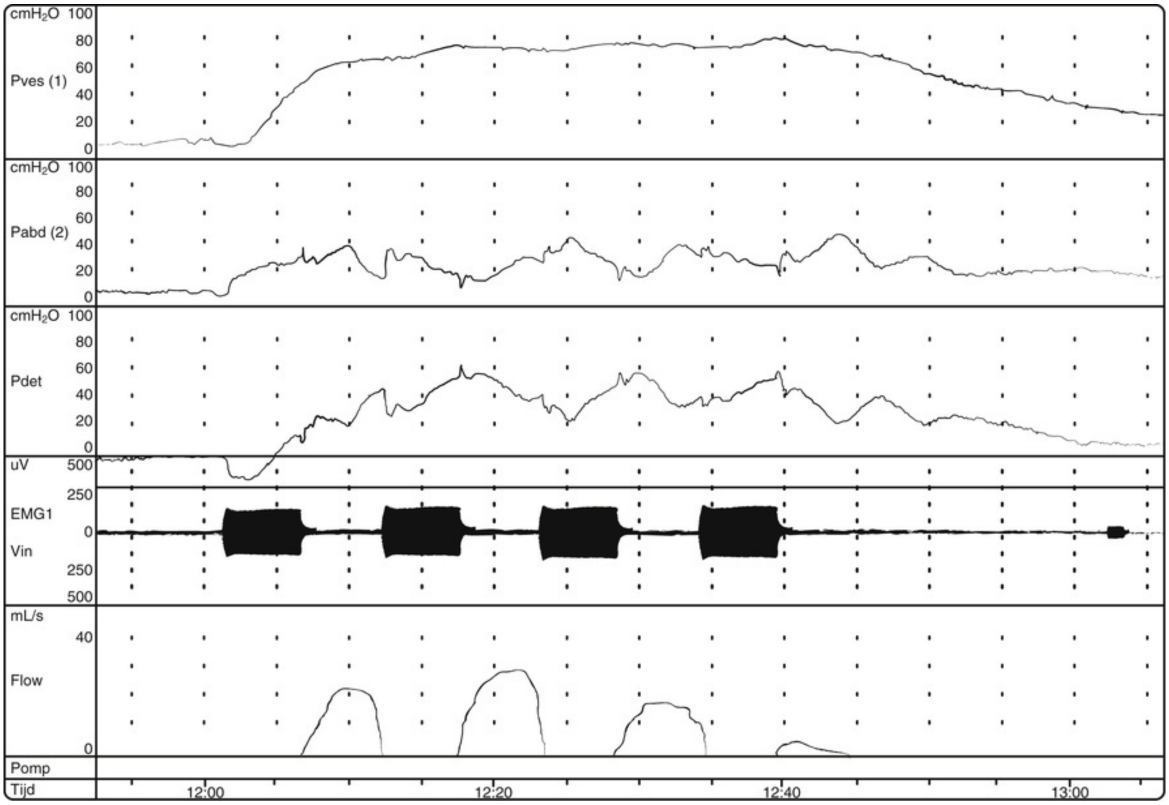

FIG. 122.1 Technique of post-stimulus voiding with the Finetech-Brindley stimulator. The three upper traces show the intravesical (Pves), intra-abdominal (Pabd), and detrusor pressure (Pdet) during stimulation. The increase in EMG signal reflects the activation of the stimulus during 5 seconds. Stimulation is activated every 12 seconds. The intermittent stimulation pattern allows the urethral sphincter to relax while the detrusor continues contracting and detrusor pressure remains elevated. This results in an intermittent flow pattern.

The motor components of the micturition reflex are composed of the PMC and its descending pathway to the sacral cord (see Fig. 122.1). The PMC is located in the dorsolateral pons, and its long descending axons make direct contact via their excitatory terminal boutons with the parasympathetic preganglionic motoneurons in the intermediolateral cell column in the sacral cord (Blok et al., 1997a,b,c). These excitatory terminals contain the neurotransmitter glutamate (Matsumoto et al., 1995). The cholinergic parasympathetic preganglionic motoneurons send their axons to the parasympathetic postganglionic neurons in the bladder wall (De Groat et al., 2015). The descending pathway from the PMC makes direct excitatory glutaminergic contact with inhibitory interneurons in the sacral intermediomedial cell column via collaterals (Blok et al., 1997a,b,c). These inhibitory interneurons contain GABA and glycine (Blok et al., 1997a,b,c; Sie et al., 2001) and send their axons to the motoneurons of the EUS (Konishi et al., 1985). Stimulation of the sacral intermediomedial cell column of the cat results in a strong relaxation of the EUS, mimicking the relaxation of the sphincter during micturition (Blok et al., 1998a,b). In mammals, activation of the PMC results in urethral sphincter relaxation via the indirect pathway to the inhibitory sacral interneurons, followed by a bladder contraction via the direct pathway to the bladder motoneurons. This bimodal activation is simultaneous at the level of the sacral spinal cord and has an immediate relaxing effect in the striated EUS and a delayed contracting effect in the smooth detrusor muscle. The PMC is the final common pathway or micturition switch for the relaxation phase, involving the EUS, and the contraction phase, involving the smooth muscle of the urinary bladder. The thoracolumbar segments T10 to L2 contain sympathetic preganglionic motoneurons, which are involved in the relaxation of the bladder wall. Efferent nerves travel within the hypogastric nerve via the thoracolumbar sympathetic ganglionic chain to the bladder wall. The sympathetic tone keeps the intravesical pressure low during end of the storage phase. The sympathetic nerves to the bladder only start to fire at about 60% of bladder capacity (Vaughan et al., 1992). Furthermore, resection of the sympatholytic drugs or resection of the sympathetic chain have little effect on bladder storage (Fowler et al., 2008). The sympathetic system is therefore supposed not the provider of continence during most of the time in healthy subjects.

The PMC receives input from the mesencephalic PAG, which is thought to be a crucial component of the micturition reflex in higher mammals. The PAG is a midbrain area initially appreciated for its role in pain modulation (Basbaum and Fields, 1984). In recent years it has become clear that this dense neuronal matter, which abuts the aqueduct of Sylvius, is essential for many vital basic functions, including respiration, aggression, mating, defecation, and micturition (Dampney, 2015; Holstege, 2014). In the cat, anterogradely labeled fibers from the lumbosacral spinal cord form a dense terminal field particularly in the lateral PAG (Blok et al., 1995). Furthermore, bladder and pelvic nerve stimulation evokes activation of the PAG (Noto et al., 1991). The importance of the PAG in the cat is exemplified by the observation that electrical stimulation of the lateral PAG results in micturition in cats, which includes an initial relaxation of the EUS followed by a bladder contraction (Blok and Holstege 1997; Taniguchi et al., 2002). Disconnection of the PAG from the PMC results in an extreme form of urgency urinary incontinence (UUI), in which the bladder empties completely after minimal filling (Ruch and Tang, 1956). The forebrain controls the PAG and the PMC like a switch, which means that when this PMC switch is not turned on, the relaxation of the EUS—the first stage of voiding—does not happen. Lesions rostral to the mesencephalic PAG result in the loss of control of the timing of micturition, but the micturition reflex remains intact. A pivotal role for the PAG and PMC in bladder control has been described in humans using positron emission tomography and fMRI (Blok et al., 1997a,b,c, 1998a,b; Griffiths et al., 2005; Michels et al., 2015). Afferent information from the bladder and urethra is relayed via the thalamus to the cingulate and insular cortices. These areas help to decide whether it is safe to start voluntary voiding via the prefrontal cortex (Blok et al., 1997a,b,c). Urinary continence is controlled by the pontine continence center or L-region (Blok, 2002; De Groat et al., 2015). The pontine continence center continuously excites the EUS during continence (see Fig. 122.1). This tonic contraction is interrupted six to seven times per day by the relaxation of the sphincter by the PMC during micturition. Furthermore, this continuous and involuntary EUS contraction cannot be stopped by the verbal command or instruction to relax the pelvic musculature. Pelvic floor rehabilitation by physiotherapy or Kegel exercises works by voluntary contraction by the primary motor cortex on top of the involuntary tonic contraction (Blok et al., 1997a,b,c). When this voluntary pelvic floor contraction stops, the contraction state returns to the baseline involuntary contraction. This explains why physiotherapy is usually ineffective in urinary retention.

Sacral Anterior Root Stimulation and Sacral Dorsal Rhizotomy

In 1969 Giles Brindley invented and introduced sacral anterior root stimulation (SARS) (Brindley and Craggs, 1978). Brindley's SARS stimulated the anterior sacral roots responsible for the contraction bladder and rectum to induce voiding and defecation. Moreover it was possible to achieve penile erection by electrical anterior root stimulation. Because anterior stimulation is not able to overcome DO and therefore could not abolish incontinence because of DO, SARS was later combined with a sacral dorsal rhizotomy of the same roots. During the last 25 years this combination of rhizotomy and electrical stimulation of the sacral roots has resulted in a significant improvement in the QoL of many paraplegic and tetraplegic patients by enhancing the functioning of their pelvic organs. The device is known as the Finetech-Brindley System (Finetech Medical Ltd., Welwyn Garden City, UK).

Stimulator

The Brindley system is composed of an external and implanted part. The implanted part can be positioned intradurally or extradurally. The implant consists of electrodes, connecting cables, and a receiver block. Patients have to put the external stimulator on the skin over the implanted receiver to evoke stimuli. The receiver is activated by the chargeable external stimulator and does not have an energy source. Electrical stimuli are evoked by radiofrequency waves. With the possibility of separate stimulation with various stimulation settings of individual sacral anterior roots (S2, S3, or S4; sometimes S5), it is possible to apply various stimulation programs to optimize micturition, defecation, and penile erections.

For intradural application, a tripolar electrode cuff is used for stimulation of the sacral anterior roots. A three-channel implant is composed of two electrode groupings. The upper grouping contains three parallel slots for right S3 root (one slot lateral right) and right and left S2 roots (two roots in one middle slot) and the left S3 root (one slot lateral left). The lower grouping contains one slot for both S4 roots. Each slot contains three metal strips acting as cathode or anode. There is one cathode in the center and an anode at each of the two ends. With this setup one can avoid to leak electrical currents at nerves outside the slot. The two-channel implant allows stimulation of two root levels or sets of root levels. The four-channel implant has the same configuration as the three-channel implant but allows independent stimulation of four sets of roots. The choice of the number of channels depends on the number of different rootlet combinations that have to be able to be stimulated. Each channel is connected to the subcutaneous receiver block by a silicone-coated cable (Fig. 122.2).

FIG. 122.2 The implanted Finetech-Brindley sacral anterior root stimulator and the external stimulator. The user selects one of the stimulation programs (for voiding, defecations, or erections) on the external control box. The external control box then sends power and control signals to the external transmitter block via the external transmitter lead. The user holds the external transmitter block over the site of the implanted receiver. The receiver converts the signals from the external transmitter block into electrical impulses. The impulses travel via implantable cables to the implantable electrodes. The electrodes transfer the impulses to the nerves.

Extradural electrodes are used in patients in whom intradural electrodes could not be placed because of conditions such as arachnoiditis or a previous intradural electrode implantation that failed with consequent dural fibrosis. Some centers prefer to use primarily extradural electrodes for nearly all patients. The extradural implant has three helical electrodes at its end, which are also configured with a cathode between two anodes.

An essential step of the surgical procedure is the isolation of the posterior sensory roots and anterior motor roots of spinal cord segments S2, S3, and S4. The intradural procedure requires a sacral laminectomy to accomplish this. After this, the spinal cord roots are stimulated individually with electrical currents to investigate their function.

Technique of Post-Stimulus Voiding

Most of the small-diameter parasympathetic efferent nerve fibers for bladder innervation are located in the sacral anterior roots (S2-S4/5). Small-diameter nerve fibers need a higher amplitude stimulus for excitation than large-diameter fibers. Consequently, electrical stimulation of the sacral anterior roots for detrusor contractions also causes contraction of the urethral sphincter resulting from stimulation of somatic large diameter nerve fibers at the same time. This prevents emptying of the bladder. To overcome this problem post-stimulus voiding is used. The duration of striated muscle relaxation of the urethral sphincter is shorter than the relaxation time of smooth muscles of the detrusor. When intermittent stimulation pulse trains are applied, the difference in muscle relaxation time can be used for voiding. When the stimulation stops, the striated sphincter muscle relaxes immediately, whereas the smooth muscle fibers of the detrusor continue to contract and relax slowly, which allows the patient to void (see Fig. 122.1). The intervals between two stimulation pulse trains allow a decrease of the urethral sphincter pressure, while a high intravesical pressure remains. This results in post-stimulus voiding with an intermittent pattern of the micturition flow. A comparable mechanism can used for defecation.

Goal and Effect of Dorsal Rhizotomy of the Sacral Nerves

Sauerwein (1990) structurally expanded SARS with a posterior or dorsal rhizotomy of the sacral roots S2, S3, S4, and S5, the so-called deafferentiation. A dorsal rhizotomy is important because it suppresses neurogenic DO and detrusor-external sphincter dyssynergia. This results in a low-pressure bladder without reflex contractions of the detrusor and subsequently continence. Moreover, it reduces autonomic dysreflexia (Hohenfellner et al., 2001; Van Kerrebroeck et al., 1996). Dorsal sensory roots form a reflex arch with the anterior motor roots, and this influences motor control over the bladder. Leaving the dorsal roots intact therefore leads to persistent DO. Therefore a rhizotomy is done to surgically dissect the dorsal (sensory) roots. Despite the benefits of preventing bladder reflex activity and in this way preventing incontinence, patients are sometimes reluctant to undergo this necessary surgical procedure because they feel that this surgical step is irreversible and takes away hope for future developments that may reverse the SCI and return to normal. Moreover sphincter weakness may occur after deafferentiation (Chinier et al., 2016). Patient education for these aspects is therefore paramount.

Patient Selection

A Brindley procedure is suitable for a selected group of skeletally mature patients with complete SCI and with DO. Patients with severe autonomic dysreflexia or detrusor-external sphincter dyssynergia may benefit especially from the dorsal rhizotomy. Patients with incomplete injury will lose their sensory function because of the dorsal rhizotomy and have the risk to experience pain sensation during stimulation because of an incomplete rhizotomy. Patients need to have intact efferent nerve pathways to the bladder and a contracting bladder.

Contractions of at least 50 cm H_2O in males or 30 cm H_2O in females must be present during filling cystometry (Brindley et al., 1986). If no sufficient spontaneous contraction occurs during urodynamic investigation, patients can be tested to find out whether they are fit for the procedure by rectal stimulation similar to electro-ejaculation procedures or direct needle stimulation of the sacral roots to provoke bladder contractions. Preoperative magnetic resonance imaging

(MRI) is performed to exclude fibrosis of the cauda equina, which precludes the intradural approach.

Surgical Implantation Technique

Laminectomy from L3-L4 to S1-S2 is performed for an intradural rhizotomy and intradural implantation of the electrode book. The dura and arachnoid membrane are opened in the midline to expose the sacral nerve roots. The anterior and dorsal components of the roots, especially relevant anterior roots for micturition, can be identified intradurally by electrical stimulation of these roots. If the roots innervate the bladder, increase in detrusor pressure can be observed during intraoperative urodynamic monitoring. At the same time blood pressure and somatomotor response monitoring is performed to identify any systemic or cardiovascular effects. After the anterior roots are separated from the posterior roots, posterior rhizotomy of the identified posterior sacral roots is done. The anterior sacral roots are positioned into the corresponding slot of the electrode cuff. After the electrode group is closed, the dura will be closed with a watertight closure to prevent dura leaks. The connecting cables of the electrode book are subcutaneously tunneled to a subcutaneous pocket for the receiver. Implantation of extradural electrodes requires a laminectomy from L5-S1 to S3-S4. The dorsal rhizotomy is done at the level of the ganglia of S2-S5. Electrical stimulation tests are used to identify the anterior and dorsal component of the sacral roots. The extradural electrode is implanted and fixated to the nerve using a strip of silicone rubber sheet, which is sutured to itself and surrounds the nerve. The connecting cables and receiver are implanted the same way as for the intradural procedure (Fig. 122.3). Fig. 122.4 shows the intradural situation after implantation of the anterior right and left S2, S3, and S4 roots in the electrode book.

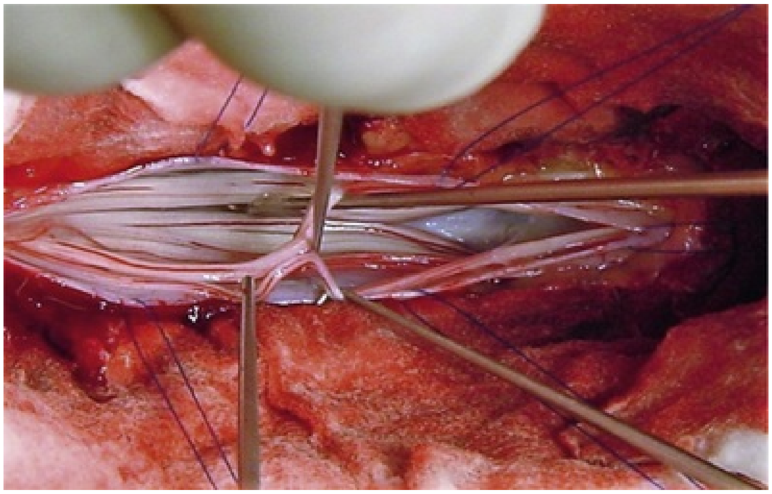

FIG. 122.3 Intraoperative photograph of the intradural anatomy after opening the dura mater at cauda equina level via a laminectomy. Stay sutures are used to expose the sacral nerves. The nerve roots of the left and right S2, S3, and S4 can be seen. The anterior roots and the posterior roots run together intradurally and have to be separated. The photo shows how the anterior root is separated from the posterior root. The anterior roots usually are small and have to be preserved; the posterior roots are thicker and have to be rhizotomized. The separation is done by so-called nerve hooks as can be seen on the photo.

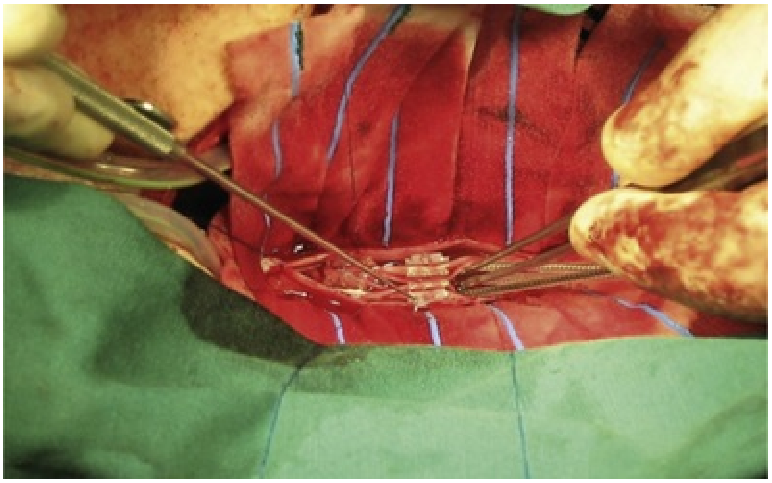

FIG. 122.4 Photo of the intradural situation after implantation of the electrodes combined in the electrode book. After separation of the sacral nerves the sensory posterior roots are rhizotomized or cut. The motoric anterior roots are placed in the electrode book. What can be seen is that the right and left S3 anterior roots are placed separately in the two outer slots of the proximal electrode book. The anterior right and left S2 roots are placed together in the middle slot of the proximal electrode book. The anterior right and left S4 root are placed in the distal single slot of the

electrode book.

Clinical Results

Table 122.1 shows an overview of publications on the clinical results of the Brindley procedure (Martens and Heesakkers, 2018). These results include those obtained by anterior stimulation by the Finetech-Brindley stimulator, which enables micturition, defecation, and erections, as well as the dorsal rhizotomy to achieve continence.

This overview includes several multicenter studies ([b]), which include overlapping results with the reports of various single-center studies. Therefore no accumulation of results is possible. (-), Unreported data or incomplete data for calculation; *UTI,* urinary tract infection.

The stimulator can instigate micturition in 73% to 100% of patients during follow-up. However, stimulation is not always completely successful, and the results include patients who use additional methods to empty their bladder. The number of patients who have residual urine of 50 mL or less is lower than the number of patients who use the stimulator for micturition. Additional methods for bladder emptying comprise intermittent catheterization, abdominal straining (Valsalva maneuver), abdominal compression (Credé maneuver), or suprapubic tapping to evoke reflex contractions.

Continence is achieved in 57% to 100% of patients, and bladder capacity increases substantially and may be more than doubled. Results on continence also included additional treatments, such as anticholinergics and stress incontinence surgery.

Overall, patients have less urinary tract infections compared with the situation preoperatively.

The Finetech-Brindley stimulator is used for defecation in 29% to 100% of patients, but success is achieved in different degrees. Not all patients achieve complete evacuation of defecation using only stimulation. Some patients need laxatives in addition to prevent constipation or enable defecation. Many patients only use the stimulator to move the stool into the rectum, whereafter they use digitation for emptying.

Erections can be evoked in a substantial number of patients, but rigidity varies considerably. This explains the relatively low number of patients who actually use the stimulator for sexual intercourse (0–32%). Rigidity can be inadequate for sexual intercourse or deteriorates over time.

Autonomic dysreflexia is mostly modulated after the Brindley procedure as a result of the dorsal rhizotomy, although there are some case reports of stimulation-induced autonomic dysreflexia.

Current and Future Perspectives for Neurostimulation

The ultimate treatment of neurourologic disorders of the lower urinary tract would be to remedy the neurogenic disorder that causes the LUTD. As long as the reversible restorative treatment is not available, symptomatic treatment options are required. Intradetrusor botulinum toxin A injections are now commonly used, often in combination with (intermittent) catheterization. However, the Brindley procedure has several advantages for suitable patients compared with botulinum toxin A, especially if other than urologic organ systems are taken into account. SCI comprises a variety of linked, physical problems. Therefore management of multiple organ dysfunctions should be advocated. The Brindley procedure not only enables continence and micturition but also completes defecation or improvement of defecation pattern, penile erections, and reduction of autonomic dysreflexia and spasms. Patients do not need assistance for intermittent catheterization and can empty their bladder at will. When the treatment options are discussed with a patient, this more extensive application of the Brindley procedure should be mentioned.

The Brindley procedure generally shows good clinical results for restoration of function in SCI patients with multiple organ dysfunction, including bladder, bowel, and erectile dysfunction. Moreover, the Brindley procedure improves QoL (Martens et al., 2011). Recent publications show that it is also cost effective.

The procedure is also relatively easy to perform. However, not every patient is suited for the procedure, and the success depends on selection of appropriate patients. Prerequisites are a complete spinal cord lesion (because neurostimulation can cause pain in incomplete spinal cord lesions), an intact sacral motor neuron pathway enabling stimulation of the bladder, and a detrusor muscle that is capable to contract on stimulation. Second, a dorsal rhizotomy and implantation of a Brindley stimulator is complex and not a routine procedure for urologists and should be reserved for specialized centres. Third, the technique is also prone to failures.

A main issue for patients who consider a Brindley procedure is the irreversibility of the rhizotomy and the possibility that future treatment options are not within reach anymore. Although SARS can restore penile erections after a rhizotomy, qualitative useful stimulation of erections is not possible in a substantial number of patients. New techniques to avoid dorsal rhizotomy are sought. Continuous or conditional neuromodulation, selective anodal block, and high-frequency block could be of help for this in the future, but so far the clinical applications of these innovations are very limited (Boger et al., 2008; Brindley and Craggs, 1980; Hansen et al., 2005; Kirkham et al., 2001; Rijkhoff et al., 1997; Seif et al., 2002). The Brindley implant is not approved by the US Food and Drug Administration (FDA).

Working Mechanism of Electrical Stimulation in Non-Neurogenic Storage and Voiding Disorders

It can be expected that electrical therapies aimed at functional bladder disorders not only target the lower urinary tract or the spinal cord but also influence higher brain centers, which, in turn, may modulate the micturition reflex components.

Several theories have been proposed on how electrical stimulation can restore normal function in bladder disorders, but none of these have been confirmed or substantiated. The suggested theories are usually focused on the working mechanism of SNM. Other relevant forms of electrical stimulation are not taken into account. However, it can be assumed that there are strong similarities among all neuromodulatory options, such as PTNS, transcutaneous electrical nerve stimulation (TENS), dorsal genital nerve stimulation, intravaginal stimulation, and intravesical stimulation (IVES). The main difference with those alternative therapies is that the SNM recruits at least 1000 times more axons by stimulating the sacral root and not a small nerve or some superficial nerve fibers. Moreover, SNM provides continuous stimulation as opposed to the other treatment options, which use a stimulation protocol of 30 minutes every 1 to 2 weeks. The implanted neuromodulator offers more flexibility in the stimulation parameters.

Another important aspect is the possible common mode of central involvement in electrical stimulation of the lower urinary tract and that used in other diseases, such as fecal incontinence and chronic pain, or even with deep brain stimulation for neurologic and psychiatric diseases.

Bladder overactivity with or without urinary incontinence is believed to be caused by a loss of voluntary inhibitory control, which emerges during the postnatal maturation of the voiding reflex. SNM may help to restore this voluntary inhibitory control (Fig. 122.5).

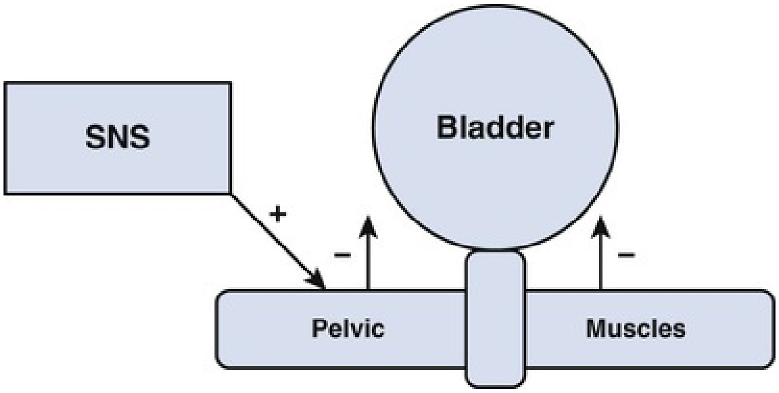

FIG. 122.5 Early theory on working mechanism of electrical stimulation in idiopathic bladder dysfunction. *SNS,* Sacral nerve stimulation.

The early theories of the mechanism of electrical stimulation in voiding dysfunction assumed that stimulation of motor nerves resulted in pelvic muscle contraction (see Fig. 122.1). This pelvic muscle contraction, in turn, would relax the bladder muscle via intramural postganglion cells (Tanagho and Schmidt, 1988). This early theory is now less plausible, because a pelvic floor contraction elicited by SNM is not necessary for a beneficial effect. Furthermore, activation of exclusive sensory nerves such as the dorsal clitoral and dorsal penile nerves results in similar effects on the bladder as SNM (Goldman et al., 2008; Groen and Blok, 2015). A similar theory was put forward for underactive bladder (Leng and Chancellor, 2005), in which SNM would inhibit the excitatory outflow via the efferent axons in the pudendal nerve. This sphincter suppression would facilitate bladder emptying (Fig. 122.6).

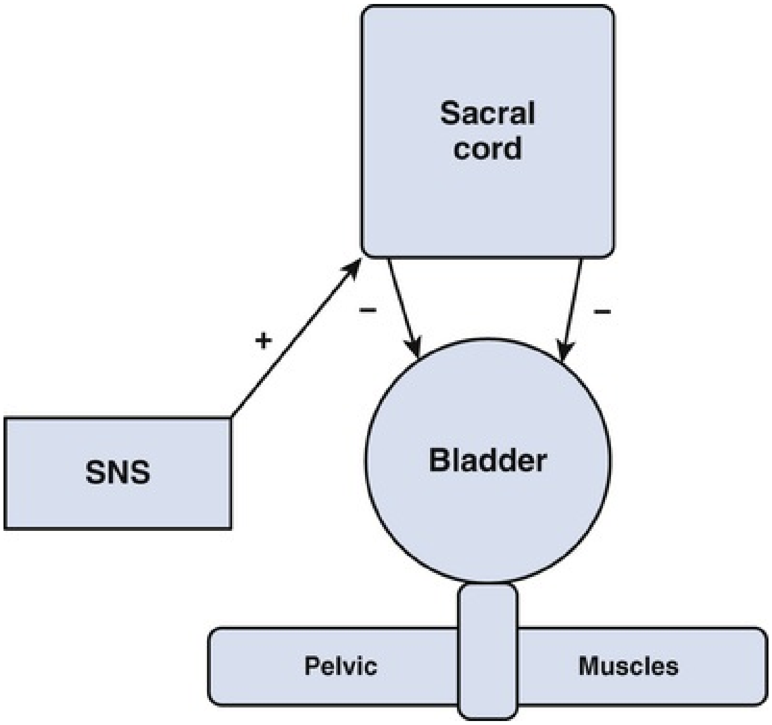

FIG. 122.6 Spinal cord theory on working mechanism of electrical stimulation in idiopathic bladder dysfunction. *SNS,* Sacral nerve stimulation.

In 2005 (see Fig. 122.2) it was suggested that the sacral cord may have a prominent target of SNM (Leng and Chancellor, 2005). The afferent pathways projecting to the sacral cord may inhibit OAB contractions by inhibiting local sacral interneurons and direct inhibition of the preganglionic parasympathetic bladder motoneurons. The same authors discussed the alternative theory that SNM would inhibit the PMC activation and, in turn, would decrease OAB contractions (Fig. 122.7).

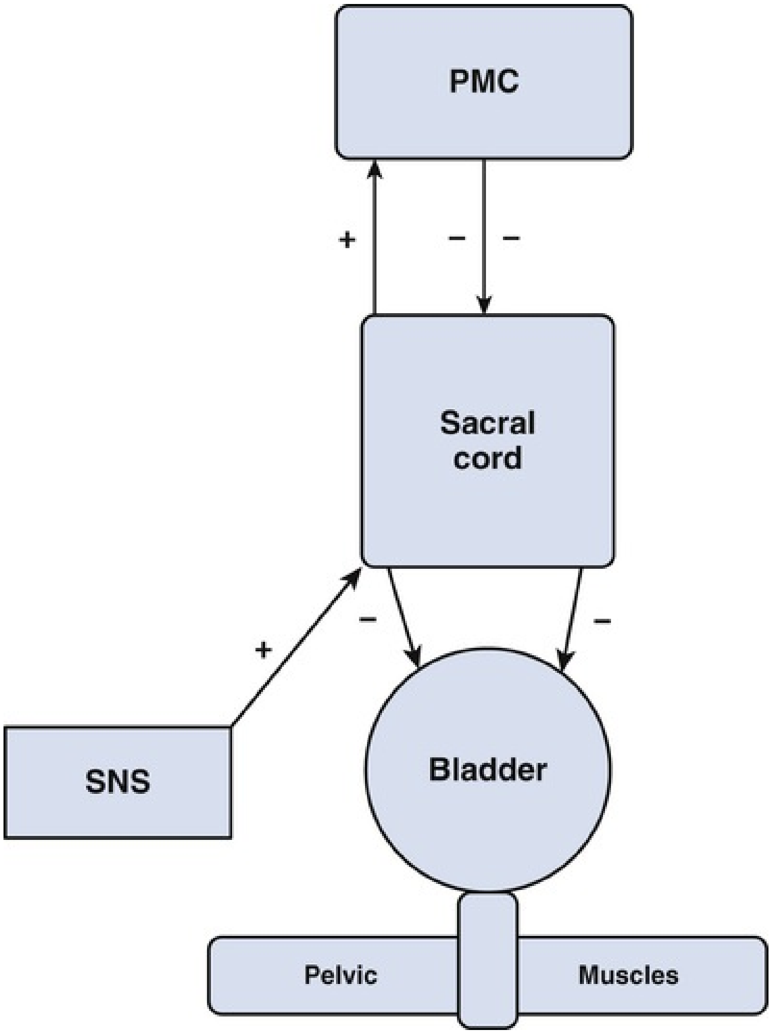

FIG. 122.7 Spinal cord-pontine micturition center theory on working mechanism of electrical stimulation in idiopathic bladder dysfunction. *PMC,* Pontine micturition center; *SNS,* sacral nerve stimulation.

Later, higher brain areas were also incorporated into relevant theories. Cortical sensory areas of the brain may be altered by SNM. Positron emission tomography showed differences in regional cerebral blood flow during acute and chronic SNM (Blok et al., 2006). The primary and associative sensory cortices were not the only areas modulated during SNM; modulation was also seen in areas important for attention and alertness. The results also suggested that chronic SNM induces neuroplasticity (Blok et al., 2006) (Fig. 122.8).

FIG. 122.8 Forebrain theory on working mechanism of electrical stimulation in idiopathic bladder dysfunction. *PMC,* Pontine micturition center; *SNS,* sacral nerve stimulation.

At present (see Fig. 122.6), it is thought that SNM activates afferent pathways that modulate forebrain structures involved in awareness and alertness. This modulation in patients with OAB results in less firing of the PMC, thereby restoring normal urinary continence. Patients with an underactive bladder lack an effective sensation of bladder filling, which does not lead to activation of the

PMC switch. SNM results in an increased awareness of bladder filling and pelvic floor contraction state. This awareness makes it possible for the patient to turn on the micturition switch and effectively relax the EUS via the PMC. In our view, SNM exerts its beneficial effect in underactive bladder mainly via relaxing the striated sphincter mediated by the descending pathways from the PMC and much less primarily via contracting the smooth muscle of the bladder.

Techniques of Electrostimulation of the Lower Urinary Tract

Intravesical Stimulation

Intravesical stimulation (IVES) first was attempted by Saxtorph to treat detrusor underactivity and urinary retention by inserting an active electrocatheter into the bladder with a neutral electrode placed in the skin (Madersbacher, 1990).

The main mechanism underlying IVES is thought to occur from direct field stimulation of Aδ afferents from low-threshold bladder mechanoreceptors, which make up the sensory system responsible for initiating and maintaining the micturition reflex (Jiang, 1998). Intact pelvic nerve afferents are necessary to provide adequate afferent feedback to generate effective bladder contractions to empty the bladder. Effects of IVES remain controversial: some studies have shown successful outcome, but other studies did not achieve dramatic effectiveness (Gladh et al., 2003; Hagerty et al., 2007; Kaplan, 2000; Madersbacher et al., 1982).

The technique of IVES is performed by inserting a sterile catheter with a connected active electrode via the urethra into the bladder. The bladder is filled with a solution that can conduct electrical currents like saline. A ground or neutral electrode is mostly attached to the abdominal skin above the pubic bone. The active electrode and the ground electrode are connected to the stimulator. Various stimulation parameters can be used: monopolar square pulses or biphasic pulse waves; amplitudes ranging from 1 up to 100 mA, pulse frequencies from up to 50 Hz, and the pulse widths ranging from 200 to 800 ms. Then a number of treatment sessions start in an outpatient session or at home.

There are few clinical studies that describe the results of this intervention. Gladh et al. (2003) applied IVES in 44 children with detrusor underactivity of various origin. Long-term normalization of the voiding after a mean of 2.5 years follow-up was obtained for 20 out of 24 children with idiopathic problems (83%) and 8 out of 20 with neurogenic problems (40%). Another 4 had much improved bladder function. The neurogenic group required more stimulation sessions than the idiopathic group. Of 15 patients on intermittent catheterization who completed IVES, 11 could discontinue the catheterization. They concluded that IVES is a promising method to treat the underactive detrusor in children.

Recently, Deng et al. (2017) published their 8-year results of IVES on detrusor underactivity in 105 patients. Of the 105 patients with different causes for detrusor underactivity (incomplete SCI 23, complete SCI 9, conus medullaris and cauda equina syndrome 36, lumbar disc surgery 15, hemorrhoid surgery 4, other causes 18) the information of residual urine volume and voiding volume was obtained in 89 patients, and pre- and post-IVES bladder sensation information was available. The patients were treated with a mean of 27 (5–181) sessions of IVES. Of the 89 patients, 47% were responders and had more than 50% reduction in the postvoid residual (PVR). Voiding efficiency of more than 50% defined as:

$$\text{Volume voided}/(\text{Volume voided}+\text{PVR})\times 100\%$$

was seen in 30% of the patients. Their analyses showed that patients with incomplete neurogenic lesions and post-hemorrhoidal surgery demonstrated the best significant improvements. They speculate that a full or partially complete central pathway reflex may be the premise condition. Also the results suggest that patients without central nerve damage may achieve increased success, which is consistent with the mechanism underlying IVES. They also concluded that the results were promising.

These data illustrate that IVES is possible and is applied especially in detrusor underactivity. However, the published series are small and much variation exists between devices and applied techniques. Future developments should aim at standardization with improved study methodology.

Transcutaneous Electrostimulation

Transcutaneous Tibial Nerve Stimulation

Since its clinical introduction in 1999 PTNS has been routinely available for a number of years. The technique received FDA approval in 2000 for office-based treatment of OAB and approval from the National Institute for Health and Clinical Excellence in 2006. Most treatment schedules consist of 12 outpatient consecutive treatment sessions lasting 30 minutes each, given 1 to 3 times per week. This schedule implies considerable effort for patients and clinic given 12 weekly outpatient clinic visits. Moreover after a successful 12-week treatment scheme, some maintenance program has to be undertaken to preserve the positive effects of PTNS.

Because of these limitations transcutaneous tibial nerve stimulation (TTNS) has been developed. This noninvasive treatment is safe because it uses only surface electrodes. It can be self-administered by the person at home, thus supporting self-management. Moreover it is convenient because the scheme of stimulation is decided entirely by the patient and can therefore reflect personal choices and lifestyle. However, there is a drawback: percutaneous stimulation is more effective than transcutaneous stimulation (George et al., 2013). Transcutaneous electrical currents require a higher amplitude because the skin acts as a capacitor, which is often painful. As a consequence the lower amplitude stimulation is used, which results in suboptimal stimulation parameters and effects.

The pros and cons of transcutaneous stimulation have been assessed in the systematic review by Booth et al. (2017). They assessed 10 randomized controlled trials (RCTs) and 3 prospective cohort studies involving 629 participants (437 women [70%] and 176 men [28%], with 16 [2%] participants not reported). TTNS was compared with sham, antimuscarinics, exercises as extra to first-line with behavioral therapy alone and with different stimulation sites. Idiopathic OAB was the focus of 7 of 10 RCTs. The other studies were about neurogenic OAB caused by multiple sclerosis (MS), Parkinson disease, cerebrovascular accident (CVA), and SCI. The studies were very heterogeneous in various ways, had not many participants, and often were underpowered. The stimulation intervention was not standardized across the studies, and a range of dosages were delivered. The duration of treatment program ranged from 4 to 12 weeks, and the total number of included sessions from 5 to 90 (mean 21.6, standard deviation [SD] 23). The length of individual stimulation sessions was 20 to 30. The number of weekly sessions varied from daily stimulation to twice weekly and once weekly.

With all associated limitations, results showed that 48% to 93% of participants achieved significant symptom improvement with TTNS. Meta-analysis of data from two included studies found a clinically and statistically significant reduction of 3.88 points on the International Consultation of Incontinence Questionnaire Urinary Incontinence-Short Form, which shows that TTNS is effective for OAB in older adults. Moreover the absence of any adverse events indicates safety and tolerability of TTNS for idiopathic and neurogenic OAB. Direct comparisons with PTNS do not exist yet and are sought. An important clinical issue is the place of TTNS in the OAB treatment algorithm. The review from Booth et al. suggests the potential effectiveness of TTNS for use in idiopathic OAB and its safety for treating neurogenic OAB. These findings, together with the utility of TTNS in a supported self-management regimen and the low cost of the intervention, make TTNS an attractive alternative to other regular first-line treatments.

Transcutaneous Sacral Dermatome Stimulation

Transcutaneous electrical stimulation is a recognized neurostimulatory technique that has been successfully employed in pain management. It has been suggested that the applied current is propagated from skin receptors to posterior root ganglion cells and then to spinal centers via Aβ, C, or Aδ fibers (Thompson, 1995).

Transcutaneous electrical stimulation has been applied in some studies to suppress DO resulting in OAB. Walsh et al. applied transcutaneous neurostimulation in a randomized fashion (Coba 208 neurostimulator unit, Tenscare Ltd., Surrey, UK) with bilaterally positioned skin electrodes overlying the S3 dermatomes (Walsh et al., 2001).

One hundred eleven female patients and 35 male patients with urgency incontinence were recruited for the study. The patients had neurogenic ($n = 35$) and non-neurogenic diseases. Patients were randomized into age- and gender-matched control and study groups. The mean patient age was 47 years (range, 17–79). All patients had remained refractory to an average of three previous treatments. The study group ($n = 74$) comprised 28 patients with DO and 18 with neurogenic DO. Of the 72 control patients, 27 had DO and 17 neurogenic DO. One of the observations was an increase in cystometric capacity of 50 cm H_2O. A majority of patients experienced the first involuntary detrusor contraction to be significantly increased during bladder filling with approximately 120 seconds in the non-neurogenic group and 58 seconds in the neurogenic group. The latter was not significant. The mean amplitude of neurogenic detrusor contraction went down from 36 cm H_2O to 23 cm H_2O, which was statistically significant. These results show that it is possible to increase bladder capacity and diminish DO.

Fjorback et al. evaluated the possibility for electrical stimulation of the sacral dermatomes to suppress detrusor contractions in MS patients with neurogenic DO, hereby providing an alternative to dorsal genital nerve stimulation (Fjorback et al., 2007). A total of 14 patients with MS (8 males and 6 females) with a bladder capacity of less than 300 mL and a recent urodynamic study showing DO-induced incontinence participated in the study. Three successive slow-fill cystometries (16 mL/min) were carried out in each patient. The first filling served as control filling in which no stimulation was applied. In the second and third fillings, electrical stimulation of either the DPN or sacral dermatomes was applied automatically whenever the detrusor pressure exceeded 10 cm H_2O. The control filling showed DO in 12 of the 14 patients. In contrast to dorsal genital nerve stimulation, electrical stimulation of the sacral dermatomes failed to suppress detrusor contractions in all patients. They concluded that although therapeutic effects may be present from stimulation of the sacral dermatomes, acute suppression of DO with sacral dermatome stimulation is not possible.

These two studies show that it is possible to have some beneficial urodynamic effects of sacral dermatome stimulation. Sacral dermatome stimulation can increase bladder capacity and perhaps reduce maximal detrusor pressures, which may be important to preserve kidney function. However, for conditional stimulation it is perhaps not useful. With conditional stimulation an attempt is made to stimulate at the occurrence of an involuntary detrusor contraction to be able to suppress it. This is appealing because it does not need continuous stimulation. However, the published investigations are scarce and the studies are not performed in many patients, so the results should be scrutinized carefully.

Percutaneous Tibial Nerve Stimulation

Neuromodulation of the lower urinary tract is extensively applied in patients with OAB complaints. The best known and best documented technique is SNS. Percutaneous tibial nerve stimulation (PTNS) also is extensively documented as an alternative way of nerve stimulation. Because PTNS is less expensive as compared with SNS, it is often named the poor man's fashion of neuromodulation. Because costs are less for PTNS, it is accessible to more patients and therefore has gained much popularity in many countries.

The innervation of the lower urinary tract originates from the lumbar, sacral, and coccygeal segmental nerves located at L2-S4 (Fig. 122.9).

Tibial

FIG. 122.9 Structure of the lower lumbar, sacral, and coccygeal nerve plexus, the merger of the various roots and the most important nerves that branches from the merged nerve plexus. The tibial nerve has its offspring in the sacral roots of mainly S2 and S3.

A network of afferent and efferent fibers is formed after exiting the spinal cord. The sciatic nerve is composed of fibers from L4 to S3 and descends toward the lower extremities (De Groat and Yoshimura, 2015). One of its distal branches is the posterior tibial nerve. Neuromodulation is postulated to be the effect of cross-signaling between sympathetic and parasympathetic postganglionic nerve terminals and synapses, causing alteration of efferent nerve signals from the spinal cord to the bladder. De Groat et al. (2015) described the different neural circuits involved in controlling the lower urinary tract. Stimulation of peripheral nerves and subsequent “cross-talk” at the level of the postganglionic neuroeffector junctions can modulate efficiency of transmission. The pudendal nerve, the dorsal genital nerve, and the posterior tibial nerve are examples of such peripheral nerves. This implies that stimulating one area of the innervations system may influence nerve behavior of other systems, which, for example, may change bladder behavior.

Some animal studies have been developed that try to elucidate the working mechanisms of PTNS in OAB. Different effects of PTNS were shown on normal reflex bladder activity triggered by intravesical saline installation versus intravesical instillation by diluted acetic acid, the latter representing a model for OAB. Opioid receptors are likely to be involved in reflex contractions seen in OAB (Ferroni et al., 2015). In the same study of cats with an intact CNS, intravenous injection with the opioid receptor antagonist naloxone blocked the acute inhibition of DO induced by PTNS in the OAB model but was unable to alter the inhibition of the normal reflex bladder activity induced by PTNS. This confirms that bladder activity in OAB is mediated via nociceptive afferent C fibers, whereas normal reflex bladder activity is mediated through Aδ afferent fibers. In one of the few studies that explored the effect of PTNS on the central nervous system, Finazzi-Agro et al. (2009) also studied information processing in the brain by recording somatosensory evoked potentials (SEP) after stimulation of the peripheral somatosensory system. Short-latency somatosensory evoked potentials (SL-SEP) and long-latency somatosensory evoked potentials (LL-SEP) were recorded before and after PTNS and sham stimulation. LL-SEP changes imply that durable changes in SEP occur. They found that the amplitude of LL-SEP changes of P80 and P100 waves in the active PTNS group was significantly higher as compared with the placebo group, suggesting long-term modifications in synaptic efficiency of the somatosensory pathway induced by PTNS. Long-term potentiation or long-term depression of excitatory synaptic transmission can contribute to experience-dependent modifications of brain function, including learning and memory. This suggests that the chronic mechanism of neuromodulation may be due to reorganization of the cortical network.

History of Percutaneous Tibial Nerve Stimulation

Peripheral neurostimulation is derived from techniques used in traditional Chinese medicine, better known as acupuncture. By puncturing specific points the Chinese attempt to restore “the energetic harmony” of the body. In 1683 a Dutch physician Wilhelmus Ten Rhyne discovered and described this Eastern traditional way of medicine in a book, *Dissertatio de Arthritide: Mantissa Schematica: De Acupunctura*. In his book he described the technique of “acupunctura” in which needles were used to treat diseases. One of the most commonly used acupuncture points used is the SanYin Jiao point, or Spleen 6 (SP-6). It is located on the medial side of the lower leg, about 6 to 8 cm cephalad to the prominence of the medial malleolus. It lies close to the medial crest of the tibia. The location of the SP-6 acupuncture point and the organs affected by its stimulation has remarkable similarities with PTNS. When electrical current is applied to the acupuncture needle, the technique is called electrical acupuncture. Especially when electroacupuncture is performed with similar stimulation parameters (2–15 Hz, 10–20 mA), it resembles PTNS (Minni et al., 1990). The main difference lies in the actual anatomic substrate used in PTNS instead of “energetic pathways” stimulated in acupuncture. McGuire et al. were the first to describe tibial nerve stimulation in 1983. He applied TTNS in 22 patients with neurogenic OAB, of whom 87% showed complete or partial improvement of their symptoms (McGuire et al., 1983). After that Stoller further developed PTNS as a treatment for OAB in pig-tailed monkeys and later human subjects with promising results (Stoller et al., 1987).

Technique of Percutaneous Tibial Nerve Stimulation

PTNS is applied in supine position with the medial malleolus pointing upward. A 34-gauge stainless steel needle is inserted approximately 3 to 4 cm, or 3 fingerbreadths, cephalad to the medial malleolus, between the posterior margin of the tibia and soleus muscle with an angulation of 60 degrees to 90 degrees. The tip of the needle has to be juxtaposed with the tibial nerve without actually touching it. Optimal depth and angulation may be varied and changed depending on patient's response. A grounding pad is placed on the same leg. The needle and grounding pad are connected to a low-voltage (9 volts) stimulator with an adjustable pulse intensity of 0 to 10 mA, a fixed pulse width of 200 microseconds, and a frequency of 20 Hz.

PTNS leads to effects in efferent and afferent nerve fibers. **Flexion of the great toe, or fanning, is a result of an efferent effect. The sensory efferent effect is a radiation tickling sensation of the foot sole. Once optimal position is ensured, stimulation is applied at an tolerable intensity level.** Based on studies most treatment schedules consist of 12 outpatient consecutive treatment sessions lasting 30 minutes given once to three times per week (Peters et al., 2010; Van Balken et al., 2001). A schematic figure is depicted in Fig. 122.10.

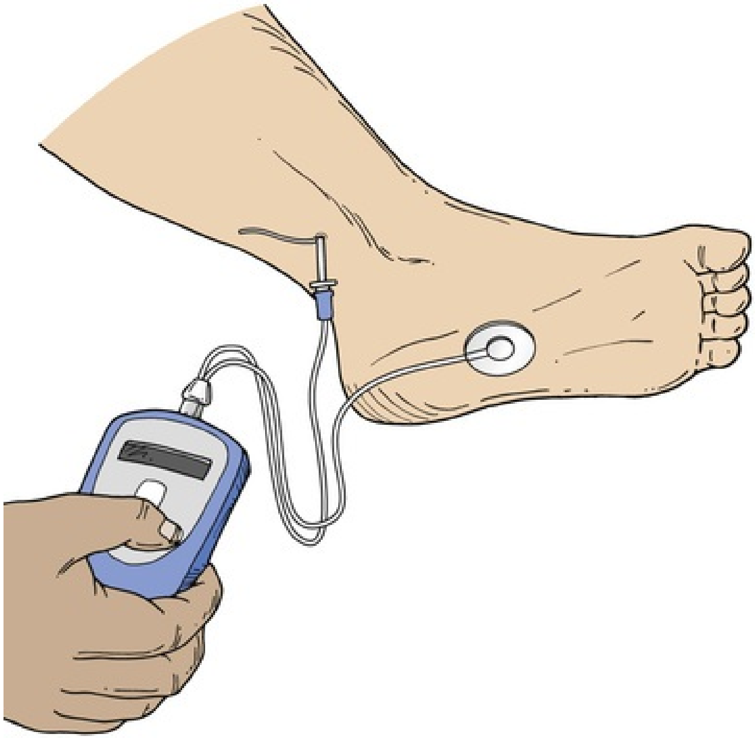

FIG. 122.10 Technique of percutaneous tibial nerve stimulation with needle at the tibial nerve, the ground pad electrode, and the stimulator.

Clinical Results of Percutaneous Tibial Nerve Stimulation

Many clinical trials have been on patients with mainly OAB symptoms. Objective outcome parameters in these studies are mainly based on frequency voiding charts (FVC), whereas subjective outcome is mostly measured by QoL questionnaires. Overall subjective success, defined as improved QoL or willingness to continue treatment, was found in 56% to 64%. Overall objective success with 50% or more decrease in urge or urgency urinary incontinence (UUI) and 25% reduction in daytime and/or nighttime frequency was found in 33% to 71% (Van Balken et al., 2001; Van der Pal et al., 2006; Vandoninck et al., 2003).

Urodynamic studies done to provide more objective data show conflicting results. PTNS performed in eight neurologic patients as soon as DO was observed during cystometry failed to suppress detrusor contractions (Fjorback et al., 2007a). Vandoninck et al. (2003) found complete suppression of DO only in a few cases, whereas others report elimination of DO in 76.9% (Kabay et al., 2008). Nevertheless, in both studies cystometric capacity increased significantly.

Peters et al. (2010) performed one of the most important studies on PTNS. In a multicenter, double-blind RCT (SUmiT trial), 12 weeks of PTNS was compared with sham stimulation. This was the first study including a validated sham arm to provide more information on the placebo effect. In total, 220 patients were included. Outcome parameters were improvement in global response assessment (GRA), FVC data including urgency, urge-incontinence, and QoL questionnaires. The GRA is a self-reported 7-point scale measuring the individual perceptive of change during treatment. Success was defined as moderate or marked improvement in the GRA. Subjects receiving PTNS showed 55% moderate or marked improvement compared with 21% in the sham group. FVC parameters after 12 weeks showed significant improvements in frequency, nighttime voids, voids with moderate to severe urgency, and UUI episodes in the PTNS group compared with the sham group. Finazzi-Agro et al. (2010) performed another sham-controlled RCT with similar results.

Thus far, no standard treatment regimen exists. Different protocols are described with the most objective data to be in favor of the 12-weeks regimen based on the previously mentioned two RCTs. Although most objective data published favor a 12-week protocol, shortened regimes may be effective as well but may be less sustainable. Until further data are published, treatment protocols remain mainly dependent on individual patient-doctor preferences.

Relapse of symptoms after successful treatment is likely to occur after PTNS. Therefore a maintenance or tapering protocol should be applied so that the brain continues to “remember” that brain control on the lower urinary tract should be sustained. Yoong et al. (2013) published the 2-year follow-up of 23 patients without deterioration of initially achieved results when a maintenance schedule was applied. The satisfaction score after 2 years of maintenance PTNS therapy was comparable with that recorded at 6 weeks (7.25/10 vs. 9.6/10, $P = 0.25$). Peters et al. (2013) followed 50 participants from the SUmiT Trial who met the primary effectiveness end point after 12 weekly PTNS. These patients were prescribed a fixed-schedule 14-week tapering protocol followed by a personal treatment. Of this group 29 patients completed the 36-month protocol receiving a median of 1.1 treatments per month. At 3 years 77% remained relapse free with 8.7 median voids per day (baseline 12.0) and 0.3 UUI episodes per day (baseline 3.3). QoL remained markedly improved from baseline through 3 years.

OAB is also a common problem in children. If standard treatment options such as behavioral therapy or urotherapy, pelvic floor therapy, and antimuscarinics fail, PTNS may be a good option. One study observed that PTNS with the percutaneous needle technique was well tolerated in 23 children with refractory lower urinary tract symptoms. In 71% of patients, symptoms improved and low scores on the visual analog scale for pain were noted, which even decreased further during the treatment period (De Gennaro et al., 2004).

Percutaneous Tibial Nerve Stimulation Compared With Other Treatments

Several studies aimed to establish the role of PTNS compared with other treatment options. Two RCTs (Peters et al., 2009; Preyer et al., 2015) compared PTNS versus tolterodine in patients with non-neurogenic OAB. Incontinence episodes decreased significantly after 3 months in both groups and QoL increased, but no significant treatment difference was seen between PTNS and tolterodine regarding QoL, urgency, and UUI, although fewer side effects were seen in the PTNS group.

Comparisons of muscarinics other than tolterodine with PTNS resulted in similar outcomes. A large Cochrane review compared seven trials with various types of peripheral neuromodulation (intravaginal electrical stimulation, PTNS, stoller afferent nerve stimulation, transcutaneous electrical nerve stimulation) to antimuscarinics. Subjective improvement rates were observed in favor of electrical stimulation. In 54% no improvement was seen with antimuscarinics versus 33% with electrical stimulation (risk ratio [RR] 0.64, 95% confidence interval [CI] 1.15–2.34). However, this was statistically significant only for PTNS (RR 2.21, 95% CI 1.13–4.33) and was not supported by significant differences in improvement of micturition frequency, nocturia, UUI, and QoL. The conclusion was that, although antimuscarinic therapy is a well-established therapy for OAB, the limited evidence from small trials may suggest that electrical stimulation is a better option in patients refractory to antimuscarinics (Rai et al., 2012).

Prognostic Factors for Percutaneous Tibial Nerve Stimulation

Few data exist concerning the prognostic factors for PTNS. Urodynamic studies in patients with OAB receiving PTNS suggest better treatment outcome in those patients without DO (Vandoninck et al., 2003).

Van Balken evaluated many clinical parameters in 132 patients, but most lacked any prognostic value. Only patients with a low SF-36 Mental Component Summary were especially prone to fail. These patients also scored worse on disease-specific QoL questionnaires, although there was no difference in disease severity compared with patients with good mental health (Van Balken et al., 2006). Mental health questionnaires therefore can be of help as a tool to select optimal candidates.

Implantable Percutaneous Tibial Nerve Stimulation

Because chronic stimulation seems necessary to sustain therapeutic effect, soon after its clinical introduction it was realized that the repeated visits to the clinic, once weekly or once bi- or triweekly, would finally lead to a logistic problem. Transcutaneous stimulation with surface electrodes was attempted, but results indicate that it may be less effective because of the impendence of the skin (Andrews and Reynard, 2003).

A new promising development came with the introduction of an implantable stimulator near the ankle. Van der Pal et al. (2006) were the first to study the subcutaneous implant-Urgent-SQ in 8 patients with refractory OAB. The Urgent-SQ (Fig. 122.11) was surgically implanted approximately 5 cm above the medial malleolus near the tibial nerve without exactly exposing it. During the procedure the implant was activated to confirm the correct position. Motor and sensory responses were evaluated postoperatively at day 10 and after 3 to 6 to 12 months. The primary objective was at least a 50% reduction in the number of incontinence episodes and/or voids on bladder diary. At 3, 6, and 12 months, respectively, 5, 6, and 4 patients met the primary objective. At 3- and 6-month follow-up, voiding and QoL parameters had significantly improved in these patients. At 12 months it remained stable compared with 6 months. Urinary tract infection, temporary walking difficulties, and spontaneous radiating sensations were reported as adverse events, and there was no local infection, erosion, or dislocation. As in studies concerning sacral stimulation not all patients who respond well on PTNS have similar results with the implantable device. In one patient the implant was removed because of technical failure.

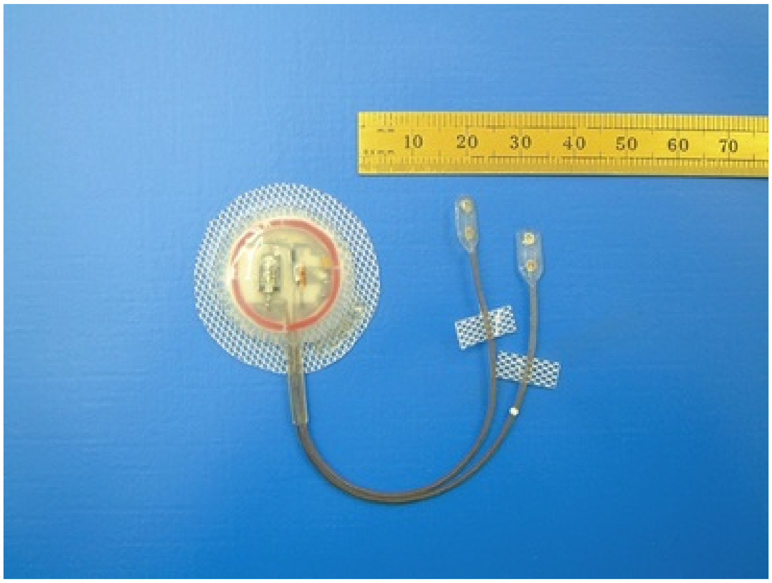

FIG. 122.11 The Urgent SQ, the first percutaneous tibial nerve stimulation implant. (Courtesy J. Heesakkers.)

Janssen et al. (2013) published the long-term efficacy and safety of these patients in an open-label study. The 7 patients with the implant still in situ were contacted after 9 years and evaluated with an interview, physical examination, ankle x-ray, voiding diaries, and completed questionnaires about adverse events, performance, efficacy, safety, and QoL questionnaires. Results showed that 6 of the 7 patients still had sensory and locomotor responses on stimulation at 9-year follow-up. Three patients, who had a successful treatment response at 1 year, still used the device. The implants were intact without migration and/or displacement. Two patients experienced minor discomfort. The conclusion was that after 9 years the Urgent-SQ implant was a safe device and well tolerated.

Recently some results of a new tibial implanted device (BlueWind Medical, Herzliya, Israel) were published (Heesakkers et al., 2017). The installation procedure was similar to that of the Urgent-SQ. In the 36 patients in whom the device was implanted, significant improvement in daytime frequency and UUI was seen. At 6 months’ follow-up 71% experienced clinical success. Leaks per day, leak severity, and pad changes per day decreased significantly over time with 28% of urgency incontinence subjects that became “dry.” Voids per day, degree of urgency, volume per void, and number of used pads also improved significantly. QoL improved as well as symptom severity scores measured by the OAB questionnaire. The listed adverse events were implant site pain in 14%, suspected infection in 22%, and procedural wound complications in 8%. A significant change was seen in 24-hour micturition frequency from a mean 12 to

8 per day. The number of severe urinary incontinence episodes decreased from 2.8 (SD 5.2) to 0.3 (SD 0.4) episodes per day. In one patient the device was explanted because of pain and swelling suspicious for infection, although tissue cultures did not reveal a bacterial infection. Implantable devices are well tolerated and safe without long-term complications. Pilot studies show promising results, but further research is necessary to establish its therapeutic value compared with conventional treatments. The Bluewind device is depicted in Fig. 122.12.

External Control Unit
(Placed above the implant)

FIG. 122.12 Schematic foot with the Bluewind implant external control unit. The device weighs 0.6 g and measures 25 mm by 3.4 mm.

Another tibial nerve implant is the Bioness Stimrouter neuromodulation system (Bioness Inc., Valencia, CA). It can be implanted under local anesthesia. It consists of a lead and an integrated receiver, which are implanted. The lead captures can be activated via a wireless external pulse transmitter and electrode patch. In July 2018 a prospective, multicenter, randomized, double-blind trial was done to look at safety and efficacy in OAB (ClinicalTrials.gov, Identifier: NCT02873312).

There are more developments with a tibial nerve implant to correct for LUTD; however, not all of them have reached the clinical stage yet nor have they been introduced into clinical practice. The Gecko 1.0 system (Nuviant Medical Inc., Dallas, TX) has only been tested in animals so far (Moazzam et al., 2017).

A new location of stimulation is the saphenous nerve, a purely sensory branch of the femoral nerve. It can be stimulated below and anterior to the medial tibial condyle. First results are promising, but there still is a long way to go (MacDiarmid et al., 2018).

Conclusions

PTNS can modulate the voiding and storage function of the bladder leading to an overall subjective improvement of symptoms in about 60% of the patients and 47% to 56% improvement of FVC parameters. Placebo effect is about 21% and even higher in children. After 2 to 3 years 53% to 77% of the patients still report improvement of symptoms if maintenance treatment is given. PTNS is minimally invasive and not very expensive, but it is time consuming. Therefore new techniques with implants are being explored, showing promising results.

Pudendal Nerve Stimulation

The pudendal nerve originates from the S2 to S4 sacral nerves and travels over the ischial spina and enters the pudendal (Alcock) canal. Proximal in the pudendal canal, it gives rise to the inferior rectal nerve, and distally it branches into the perineal dorsal genital nerve.

Low-frequency stimulation of the afferent fibers of the pudendal nerve stimulation has been shown to be an effective target to inhibit the OAB. More specifically, stimulation of the dorsal genital nerve in patients with a complete thoracic or cervical spinal cord lesion resulted in a strong inhibitory effect on the micturition reflex (Vodusek et al., 1986).

The pudendal nerve can be stimulated percutaneously via through the pudendal canal (Spinelli et al., 2005). At present this is off label with the use of a tined quadripolar lead, which is placed via a posterior approach. The perineal approach is more prone to lead infection. This approach can be used for treatment of idiopathic and neurogenic OAB and chronic pelvic pain (Heinze et al., 2015; Peters et al., 2005). Patients with voiding dysfunction who did not respond to sacral neuromodulation were selected to receive pudendal nerve stimulation. When pelvic pain is the predominant presenting complaint, it has been suggested that only bilateral pudendal leads will lead to a successful test (Heinze et al., 2015). However, the FDA has not approved chronic pudendal nerve stimulation for voiding dysfunction or pelvic pain. Furthermore, the

Conformité Européenne Mark of pudendal nerve stimulation for OAB has now expired.

Dorsal Genital Nerve Stimulation

Dorsal genital nerve (DGN) stimulation is done by means of the dorsal clitoral nerve in women and dorsal penile nerve in men.

DGN stimulation with needle electrodes is an experimental neuromodulation technique to treat neurogenic and OAB disease; however, it is not yet applied in daily clinical practice. The DGN is a branch of the pudendal nerve. Stimulating the DGN may have several advantages compared with other frequently stimulated nerves such as the sacral roots or the posterior tibial nerve. The DGN is like the posterior tibial nerve, easy accessible for needle electrodes. The nerve is also a direct branch of the pudendal nerve and has therefore quicker access and more focused access to the sacral nerves that control lower urinary tract function. Moreover, theoretically the DGN is better suited for neuromodulation of the lower urinary tract. Similar to the mechanism of neuromodulation, the first route of the neuromodulative stimulus is afferent to the brain. This implies that pure sensory nerves such as the DGN theoretically are more effective in transporting the stimulus afferently to the brain (Martens et al., 2011). Successful stimulation of the DGN can be detected by monitoring the presence of the genitoanal reflex. Martens et al. experimented with percutaneous DGN stimulation in 6 patients with SCI with proven DO. DO could be suppressed with DGN stimulation. The clinical results that have been published should be regarded with caution. Studies are mostly acute experiments and with a small number of patients. The longest-lasting study is from Goldman et al. (2008). He examined DGN stimulation in 21 female OAB-wet patients with a percutaneous wire electrode. Patients received 7 days of continuous stimulation, and all but 2 completed the study (*n* = 9). In 47% of the patients, there was a reduction in incontinence episodes/day of more than 50%, and 81% of patients had a reduction of severe urgency episodes/day of more than 50%. The results of a pilot study by Van Breda et al. (2016) was also promising but had limited follow-up.

This study investigated on-demand DGN stimulation through a percutaneously placed wire electrode in six patients with non-neurogenic OAB. The idea is that with on-demand stimulation, when patients experience urgency, activation of a stimulating device that suppresses urgency is more effective because it is not influenced by habituation and is more efficient because it uses less energy. Overall, 73% reported improvement in symptoms, including urgency and incontinence severity. Although DGN stimulation is promising and has shown some good results, larger study cohorts are needed to determine the applicability of this type of neuromodulation. The drawback so far is that it is not easy to fix the stimulating electrodes in such a way that they keep in close contact with the small DGN branches. Moreover the area of stimulation, the dorsal base of the penis or the clitoral area, may be problematic for patients.

Sacral Nerve Stimulation

Sacral neurostimulation (SNM) is an effective third-line therapy in patients with OAB. The working mechanism of electrical therapy in bladder dysfunction including SNM has been discussed in the previous paragraph. The clinical use and outcomes of SNM are described for several forms of bladder dysfunction.

Current Indications and Outcomes for Sacral Neuromodulation

The American Urological Association and European Association of Urology recommend SNM as a third-line treatment option when first-line treatments (e.g., lifestyle intervention and pelvic floor exercises) and second-line treatments (e.g., medication) have failed in patients with idiopathic OAB symptoms. The first approved sacral neuromodulator, Interstim (Medtronic, Minneapolis, MN), received a CE Mark in Europe in 1994 for the treatment of functional disorders of the pelvis and lower urinary or intestinal tract. In 1997 Interstim was approved by the FDA for the treatment of UUI, and in 1999 for urinary urgency-frequency and urinary retention. The updated neuromodulator Interstim II received a CE Mark in 2006. The Interstim therapy uses a non-rechargeable voltage driven battery. It was in 2004 the rechargeable battery became available for spinal cord stimulation in chronic pain patients. At this time, there is no rechargeable battery available for urologic patients in the US market.

Overactive Bladder With or Without Urinary Incontinence

The International Continence Society definition of OAB with urinary incontinence is any involuntary urinary leakage which is preceded or accompanied by urgency, a sudden compelling desire to pass urine that is difficult to defer (Abrams et al., 2002). It is generally accepted that seven times per 24 h is the upper limit of the normal voiding frequency. OAB without urinary incontinence (i.e., “urinary urgency and frequency”) is then defined as eight times voiding or more per 24 h with urgency for voiding that is difficult to defer. However, this definition does not exclude urinary frequency resulting from excessive fluid intake. It is obvious that the voiding frequency very much depends on the fluid intake. Therefore it is important to assess frequency of voiding with a urinary diary before starting any treatment for OAB. Other causes, such as urinary tract infection, underactive bladder with significant postvoid residual bladder stones, and bladder cancer, have to be ruled out. Urodynamic investigation in patients with OAB may or may not demonstrate detrusor overactive contractions during the filling phase of the micturition cycle. Several studies demonstrated no association between DO and successful treatment with chronic SNM (Groenendijk et al., 2008; South et al., 2007).

Multiple studies have shown the efficacy of SNM in the short and long term, but the definition of success varies considerably among the studies. A recent prospective randomized trial (INSITE) in 147 OAB patients with mild to moderate symptoms compared SNM with standard medical treatment (Siegel et al., 2015). Intention-to-treat analysis demonstrated a 61% success rate for neuromodulation and 42% success for standard medical treatment at 6 months of treatment. In another prospective randomized study over 6 months, 34 implanted patients were observed and 42 patients, who received standard medical therapy, made up the control group (Schmidt et al., 1999). Voiding and incontinence parameters were significantly better in the SNM group compared with the control group with 76% success, including 47% completely without incontinence.

Another recent prospective randomized trial (ROSETTA) compared onabotulinumtoxinA (BTX) to SNM in 381 women (Amundsen et al., 2016). The mean number of incontinence episodes decreased more in the BTX group than in the SNM group (−3.9 vs. −3.3 episodes per day) at 6 months. However, in this study the amount of 200 U of BTX was twice the recommended starting dose for idiopathic OAB and not the standard of care for this third-line therapy. This alternative dose of 200 U was used off label before the compound was registered for idiopathic OAB, but this is not clinical practice at present because of a higher chance of adverse events such as urinary retention and urinary tract infection (Dmochowski et al., 2010). The registered dose BTX for idiopathic OAB is 100 U, which was significantly more effective than placebo at 4 months

(Nitti et al., 2013).

The long-term follow-up results of the ROSETTA trial were recently published (Amundsen et al., 2018). It was concluded that BTX and SNM offer sustained and equal reductions in the primary outcome urgency urinary incontinence episodes after 2 years. Higher satisfaction and treatment endorsement were maintained in the BTX group through the 24 months. Recurrent urinary tract infections were higher after BTX injections (24% vs. 10%; $P < 0.01$), and 6% required intermittent catheterization after the second injection. SNM revision was needed in 3% and removal in 9% of cases. Interestingly, the intermittent catheterization frequency was lower in the BTX group than previously reported, as were the SNM revision and removal rates, possibly because of standardized lead placement with strict treatment response criteria.

Two additional prospective cohort studies on OAB and SNM had a follow-up of at least 5 years. The study groups comprised 96 male and female patients and 60 female patients, respectively (Groen et al., 2011; Van Kerrebroeck et al., 2007). Significantly fewer incontinence episodes were found in 58% and 50% of the patients, respectively, and in 61% and 53% (significantly) less use of pads.

Nonobstructive Chronic Underactive Bladder (Voiding Dysfunction)

Nonobstructive chronic underactive bladder is defined as a nonpainful bladder with a chronic high postvoid residual, which necessitates regular drainage of the bladder. The amount of clinically accepted urinary residual volume after voiding is debatable but has often been defined as 100 mL. An underactive bladder is, as a rule, also hyposensitive with larger-than-normal maximum capacity of more than 500 mL. Clinically, it is critical to assess the actual residual volume because this is the only objective parameter to measure success or failure of treatment. In 1999 the FDA approved SNM for the treatment of chronic urinary retention without obstruction.

In a prospective randomized study, 68 out of 177 patients with urinary retention qualified for full SNM implantation after a test of 3 to 7 days. Of these 68 patients, 37 patients received SNM implantation and were compared with 31 patients who continued self-catherization (Jonas et al., 2001). After 6 months, 69% of the SNM patients no longer catheterized compared with none in the control group. Another retrospective study in 21 men with chronic urinary retention demonstrated a similar success rate of 67% with the notation that men younger than 43 years of age were more likely to respond.

Other Indications

SNM is not FDA approved for chronic bladder pain and neurogenic bladder dysfunction. In selected patients SNM may be offered, especially when there are also symptoms of OAB. Because measurement of change in pain perception is very subjective and strongly influenced by pain medication, the recording of OAB symptoms makes it possible to determine an objective improvement during the test phase. Most of the studies on SNM in bladder pain syndrome and chronic pelvic pain used a retrospective approach in a small number of selected patients. In a prospective study, 17 patients were treated with SNM for a mean of 14 months (Comiter, 2003). Mean voided volume increased from 111 to 264 mL, and pain decreased from 5.8 to 1.6 on a 0 to 10 visual analog pain scale. Another study with a follow-up of a mean of 86 months reported a 64% reduction of pain in 30 patients who underwent SNM (Marinkovic et al., 2011). SNM may be effective for treating neurogenic bladder patients, but, as in bladder pain syndrome, the level of evidence is low (Groen et al., 2016). A systematic review identified 224 patients in 22 studies who underwent SNM (Kessler et al., 2010). Patients with MS and SCI were most prevalent and had mainly a mix of symptoms of OAB and urinary retention. The pooled success rate was 92% after a mean follow-up of 26 months. It was concluded that the effectiveness of SNM in non-neurogenic patients and neurogenic patients is comparable (Kessler et al., 2010; Figs. 122.13 and 122.14).

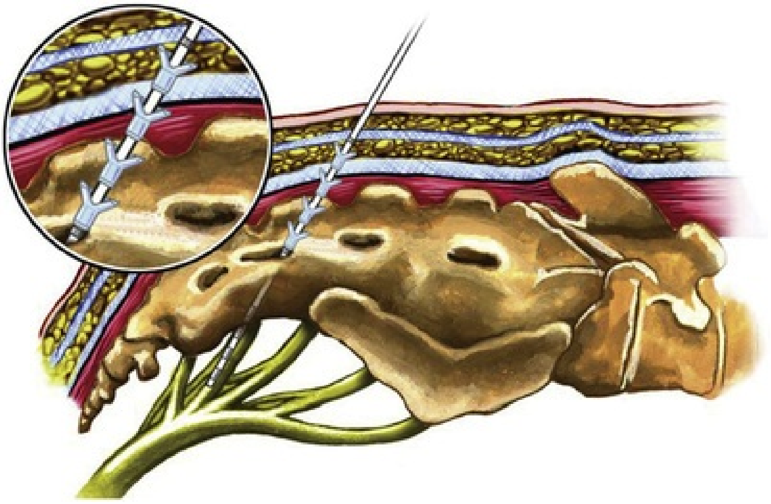

FIG. 122.13 The tined lead is introduced typically into the S3 nerve

foramen. The tines allow the lead to be fixed into the fascial layers above the sacrum. This lead has a quadripolar configuration (four contact points). (Courtesy Medtronic, Minneapolis, MN.)

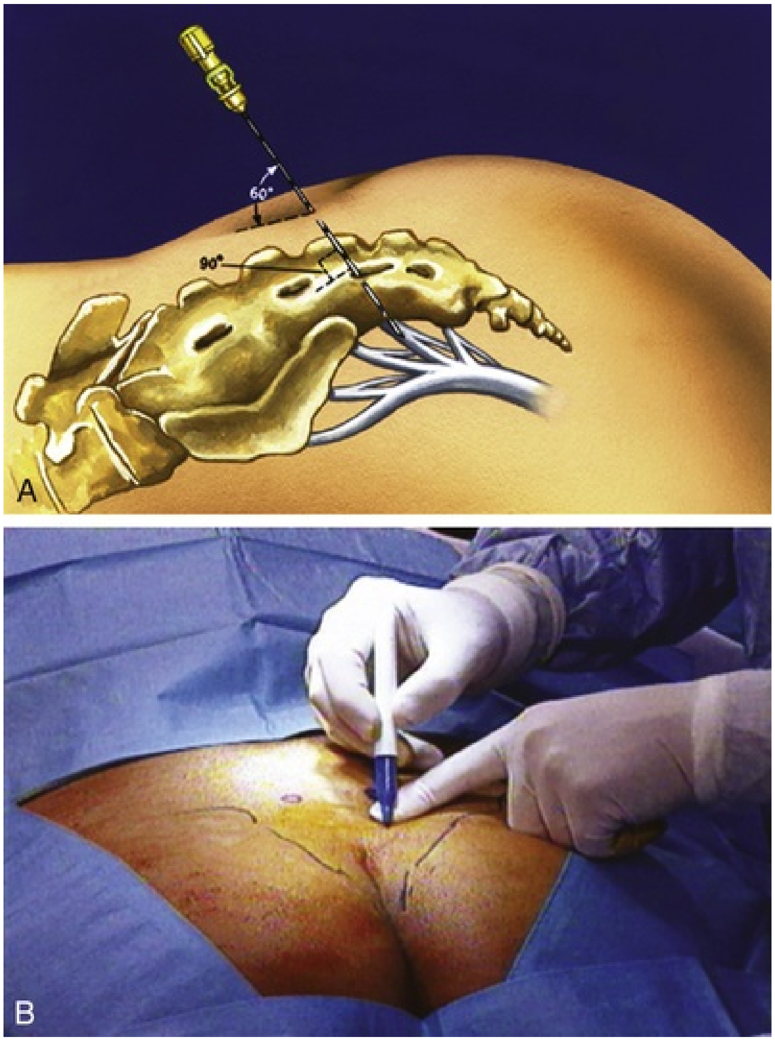

FIG. 122.14 (A) The percutaneous test stimulation is performed in an outpatient setting. A small lead wire is placed into S3 and connected to an external stimulator for 1 week to administer stimulation to the nerve roots. (B) Measurement of the S3 nerve foramen is typically 9 cm to the coccyx and 11 cm to the anal verge. To find the rough site of the S3 nerve foramen, 1 to 2 cm lateral to this mark is measured. The “cross hair” technique can be used to find the midline fluoroscopically and the lower aspect of the sacroiliac joints laterally to find the S3 nerve foramen, as well. (Courtesy Medtronic, Minneapolis, MN.)

Sacral Neuromodulation Patient Selection and Implantation

Procedure

The SNM implants are products of Medtronic and contain a lead with four electrodes and a neurostimulator, named Interstim II. The success of an implanted SNM depends to a large extent on a correct selection of the patient. Theoretically, test stimulation is not necessary and selected OAB patients receive immediate implantation of the complete SNM with a chance of success of at least 90%. However, clinical practice dictates that all candidate patients receive a stimulation test trial. The test may be done in an ambulatory environment, known as peripheral or percutaneous nerve evaluation (PNE), or can be performed with a two-stage implant in the operation room. The patient may get a complete implantation of SNM when there is 50% improvement or more in one or more of the voiding parameters: frequency of voiding, voided volume, and incontinence episodes. Comparing the baseline bladder diary filled out by the patient for 3 to 5 days before the test trial with a second bladder diary filled out during the test period constitutes the assessment.

Percutaneous Nerve Evaluation Test.

During a PNE, an insulated needle is introduced into the third or fourth sacral foramen under local anesthesia on the basis of bony landmarks, such as coccygeal bone, the iliac crest, and the lumbosacral joint. Fluoroscopy may be used during or after placement, but with respect to SNM, the anatomic location is not fully correlated with the functional outcome. Correct placement during electrical stimulation by an external neurostimulator is confirmed by induction of perineal sensations. Usually, these sensory responses precede possible motor responses, such as contraction of the external anal sphincter and flexion of the great toe. Subsequently, a temporary flexible test lead with an electrode at the tip is introduced via the needle, which is removed when the lead is in place. The lead is adhered to the skin and connected to a receiver in a belt. The receiver is wirelessly controlled by an external neurostimulator. When the patient is not distracted and is focused on the perineal area, he or she will feel a small perineal sensation, which is not painful or annoying. The test phase lasts usually 5 to 7 days, during which a bladder diary is recorded. The PNE is assumed positive when one or more bladder diary parameters shows more than 50% improvement. In our clinic the PNE test is positive in 60% of the OAB patients. We do not use the PNE test for urinary retention because of the high failure rate. When patients pass the test, they may receive the complete SNM, which consists of the quadripolar lead and a neuromodulator. The advantage of PNE is that it is an incision-free procedure performed in the outpatient clinic under local anesthesia. The main disadvantage of the temporary PNE lead is that it is prone to dislocation, which may lead to test failure.

Staged Implant Procedure.

Patients who failed or could not tolerate PNE may be offered the two-staged procedure. In response to patients who had a positive PNE but a less favorable result with complete SNM, the two-stage implant procedure was introduced (Janknegt et al., 1997). The first stage involves implantation of the permanent electrode (Fig. 122.15). Originally, the lead was placed in the S3 foramen during an open procedure via a 10-cm vertical incision over the sacral bone and after placement in the foramen fixed on the periosteum of the bone. Since 2003 such an invasive procedure is not necessary, and the lead can be placed percutaneously in the relatively short time of about 30 min (Spinelli et al., 2003). In our hospital the patients receive preoperatively the first-generation cephalosporin cefalozin and metronidazole intravenously (IV) to protect against perineal anaerobic organisms. A retrospective study on surgical site infections in patients undergoing SNM suggested adding prophylactic treatment for methicillin-resistant *Staphylococcus aureus* (Brueseke et al., 2015). The permanent lead is coupled to a temporary extension wire, which is placed subcutaneously toward the flank and connected in the same way as described for the PNE. The tunneling reduces the risk of infection, the lead is more precisely placed than the PNE lead, and the evaluation can be prolonged by up to 4 weeks while the neurostimulator program is optimized. Implantation of the neuromodulator at the buttock and removal of the extension wire follow in the second stage after 2 to 4 weeks in case of 50% or more improvement in one or more of the voiding parameters. In the case of test failure, the lead and extension wires are removed and alternative treatment options can be offered. A recent narrative review from the International Continence Society SNS consensus panel presented their recommendations on best practices for neuromodulation (Goldman et al., 2018). They concluded that the preferred target for SNM is the S3 nerve, but in some cases also S4 may be appropriate. The surgeon should strive to achieve appropriate motor and/or sensory responses on all 4 contacts at low stimulus amplitudes, but fewer than 4 contacts and/or higher voltage can be successful.

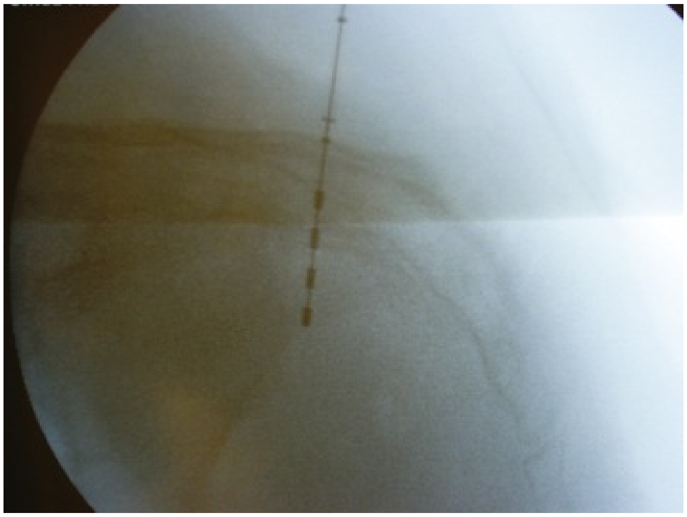

FIG. 122.15 Fluoroscopy is used to confirm lead placement, typically with the lead configurations to obtain optimal muscle (bellows response and ipsilateral toe contractions) and sensory (vaginal, penile, or scrotal "pulsating" feeling) responses. The lead then may be deployed.

The minimal invasive staged implant can be done under local anesthesia, sedation, or general anesthesia. The staged procedure results in an increased rate of implants compared with the PNE test. In a retrospective study, 69 patients with OAB and 31 with urinary retention received a PNE test followed by a staged implantation (Leong et al., 2011). Success was observed in 47% after PNE and in 69% after staged implantation.

The Interstim II neuromodulator was introduced in 2006. It has a lithium battery (1.3 A-h at 3.2 V), which is covered by a titanium box (51 × 44 × 7.7 mm). The neuromodulator weighs 22 g, and its volume is 14 cc. The voltage driven battery provides continuous or intermittent pulses from 2.1 to 130 Hz (in 49 steps) with a pulse width of 60 to 450 µs (per 30 µs). The upper limit of voltage is 8.5 V. The much larger Interstim was the precursor of the Interstim II and has not been available since July 2017. For bladder dysfunction, pulse width is set at 210 µs and rate at 10 to 16 Hz. The amplitude is set around the threshold of urogenital or anal sensation. Programming of neuromodulator ensures the optimal stimulation with the best tolerable sensation at the lowest amplitude. Stimulation can be carried out in either unipolar or bipolar fashion. After implantation and the initial programming, the neuromodulator has to be adjusted on average three times during the first year and 0.8 per year in the following years in patients with OAB (Groen et al., 2011). The durability of Interstim was around 7 years, whereas that of the smaller Interstim II is on average 4.4 years (Groen et al., 2011). A smaller neuromodulator will improve the comfort of the patient, but this comes at the high replacement rate and increased risk infection with the device and its lead around the time of operation. At Erasmus Medical Center, more than 50% of our SNM budget for 70 full implants is allocated to replacement of the Interstim II, leaving fewer resources for new patients.

Future Perspectives of Sacral Neuromodulation

No clear predictors of success have been identified, and a positive response does not lead to a successful outcome in all patients in the long term (Scheepens et al., 2002). Because SNM treatment is usually for life, other modes of battery use have been investigated.

Constant Versus Intermittent Stimulation

SNM uses a continuous stimulation protocol. Other forms of electrical neuromodulation for OAB, such as PTNS, use stimulation for 30 minutes per 1 or 2 weeks. The effectiveness of this PTNS protocol suggests that intermittent SNM stimulation may have a beneficial effect on OAB symptoms. Indeed, a prospective randomized crossover trial showed no difference of the effects between continuous and cyclic stimulation with 16 seconds on and 8 seconds off (Price et al., 2015). Another prospective cohort study in 19 patients demonstrated no difference between SNM for 8 hours on and 16 hours off and continuous SNM (T Hoen et al., 2017). Closed-loop neurostimulation is also a future possibility for SNM in idiopathic OAB. In such a stimulation protocol the electrical stimulation is only necessary just before the OAB symptoms are present. The start of the stimulation could be set on the basis of a certain bladder volume at which the first sensation is perceived by the patient or at the point that the bladder pressure increases. Both parameters, bladder volume and increased bladder pressure, could be measured directly by a microchip on the bladder or indirectly by measurement of afferent pelvic nerve activity.

Rechargeable Neurostimulator

The need for different stimulation protocols such as intermittent and closed loop stimulation to save battery life becomes less obvious with the recent introduction of a rechargeable current driven neurostimulator by Axonics. Clinical results after 3 months for the treatment of OAB in 51 patients demonstrated success in 73% after implantation of the complete device without prior test stimulation (Blok, 2017; Blok et al., 2018a,b). These results are comparable with the Interstim therapy in patients with OAB. It is claimed that this rechargeable neurostimulator can last for more than 15 years. The use of a current driven stimulation protocol results in fewer adjustments of the stimulation parameters than a voltage-driven stimulation protocol as with the Interstim II neurostimulator. An additional advantage of the rechargeable device is that it can be switched to the Medtronic lead via an extension cable when the Interstim II battery is empty. In Europe, the new rechargeable neuromodulator from Axonics received the CE Mark in 2016. It is expected that the Axonics device will receive FDA approval in 2019.

Other Issues

Some publications suggested bilateral neuromodulation in the case of failing unilateral stimulation (Marcelissen et al., 2011). This is not clinical practice because of the lack of definitive evidence of superiority compared with unilateral stimulation and the potential of increased economic burden for the health care system.

The Interstim II neurostimulator has conditional FDA labeling for 1.5 Tesla MRI head scans, but 1.5 Tesla MRI is contraindicated for the lower body, including the lower back and pelvic region. The use of 3 or 7 Tesla MRI scans or MRI scans of any part of the body is contraindicated for this device. The rechargeable Axonics neurostimulator has conditional labeling approval in Europe to safely undergo head and neck MRI scans in 1.5 and 3 Tesla environments.

Key Points: Electrical Stimulation and Neuromodulation for Lutd

- Electrical stimulation is a young but fast-growing treatment entity for LUTD.
- Nearly every nerve involved in the innervation of the lower urinary tract could theoretically be used to influence the lower urinary tract.
- SARS is very effective and improves QoL dramatically but is also very invasive and irreversible.
- The future innovation of the Brindley technique should avoid dorsal rhizotomy.
- Of the peripheral types of neuromodulation, PTNS is the best tested and developed and it has FDA approval.
- New initiatives to have more patient- and doctor-friendly techniques are in development.
- SNM is an established third-treatment option for idiopathic bladder dysfunction. SNM does have FDA approval for idiopathic OAB and nonobstructive underactive bladder but not for bladder or pelvic pain

syndrome and neurogenic bladder.

Retropubic Suspension Surgery for Incontinence in Women

Siobhan M. Hartigan MD, Christopher R. Chapple MD, FRCS (Urol), Roger R. Dmochowski MD, MMHC, FACS

Continence in women results from a complex interplay of anatomic and physiologic properties of the lower urinary tract (bladder, urethra and sphincter, and pelvic floor) acting under the coordinating control of an intact central and peripheral nervous system. The role of the pelvic floor is to provide support to the bladder and the urethra and to facilitate normal abdominal pressure transmission to the proximal urethra, thereby maintaining continence.

Stress incontinence is a symptom, a sign, and a clinical diagnosis; the clinical symptom is that of involuntary loss of urine on effort or physical exertion (e.g., sporting activities) or with increased intra-abdominal pressure, such as occurs during coughing and sneezing (Haylen et al., 2010). The International Continence Society defines urodynamic stress incontinence as the involuntary leakage of urine during filling cystometry, associated with increased intra-abdominal pressure, in the absence of detrusor (bladder wall muscle) contraction (Haylen et al., 2010). Thus urodynamic evaluation is a prerequisite for the diagnosis of urodynamic stress incontinence. Therefore, in discussing stress incontinence, this chapter refers to women with stress urinary incontinence (SUI) diagnosed on the basis of symptoms alone or as proven by urodynamics, so-called urodynamic stress incontinence.

Treatment options for SUI include conservative techniques and pharmacologic and surgical interventions. In general, surgical procedures to treat SUI aim to improve the support to the urethrovesical junction and to correct deficient urethral closure. There is a contemporary lack of consensus, however, regarding the precise mechanism by which continence is achieved in the "normal asymptomatic woman" and therefore not surprisingly in how "normality" is restored by surgical manipulation. Anti-incontinence surgery is usually used to address the failure of normal anatomic support of the bladder neck and proximal urethra, and intrinsic sphincter deficiency. **Anti-incontinence surgery does not necessarily work by restoring the same mechanism of continence that was present before the onset of incontinence. Rather, it works by a compensatory approach, creating a new mechanism of continence** (Jarvis, 1994a).

Therapeutic Options

The surgeon's preference, coexisting problems, and anatomic features of the patient and her general health condition influence the choice of procedure. Numerous surgical methods have been described, but they essentially fall into seven categories (Box 123.1).

Box 123.1

Surgical Methods

Open retropubic colposuspension
Laparoscopic retropubic colposuspension
Suburethral sling procedure
Needle suspension
Periurethral injection
Artificial sphincter
Vaginal anterior repair (anterior colporrhaphy)

This wide variety of treatment options for stress incontinence indicates the lack of a clear consensus as to which procedure is the most effective. Several groups have reviewed the literature, often using systematic and methodical analyses of well-designed randomized controlled trials (RCTs) (Black and Downs, 1996; Fantl et al., 1996; Fusco et al., 2017; Jarvis, 1994b; Lapitan et al., 2003; Leach et al., 1997; Moehrer et al., 2000, 2003). **Most of these reviews, however, are hampered by the quality of the existing evidence base, and these reviews are based on studies of mixed quality with little standardization of the points in Box 123.2.**

Box 123.2

Standardization Needed for Studies

The patients under study (with regard to age, history of prior surgery, body mass)

The nature of the surgical technique, taking into account the surgeon's experience
Outcome measures and follow-up

A review of existing literature on confounding variables affecting outcome of therapy (Rovner et al., 2017) concluded the following:

1. **Age may not be a contraindication to colposuspension:** Success in the elderly was equivalent to success in younger patients at long-term follow-up in some studies (Gillon and Stanton, 1984; Tamussino et al., 1999), although others have reported less success with increasing age (Chilaka et al., 2002; Langer et al., 2001). Smith et al. (2009), from their review of the literature, concluded that the effect of age on outcomes is poorly defined. The Stress Incontinence Surgical Treatment Efficacy study investigated the effect of age on perioperative and postoperative outcomes of pubovaginal slings and colposuspension (Richter et al., 2008). Overall, compared with younger women (mean age 49.4 years), older women (mean age 69.7 years) took longer to return to normal activities (50 vs. 42 days; $P = 0.05$), but there was no difference in return to normal voiding. The older group were more likely to have a positive stress test at follow-up (odds ratio [OR] 3.7; 95% confidence interval [CI] 1.70–7.97; $P = 0.001$), less subjective improvement in stress and urgency symptoms, and more likely to require repeat surgery (OR 3.9; 95% CI 1.30–11.48). The effect of aging on the lower urinary tract includes a higher rate of detrusor overactivity as well as urgency incontinence and intrinsic sphincteric deficiency (ISD). In addition, older patients are more likely to have had prior interventions and may therefore have a higher rate of periurethral fibrosis and/or other abnormalities in the tissues surrounding the lower urinary tract. The presence of multiple comorbidities may also affect overall surgical outcome, including creating the possibility for increased complications and a prolonged postoperative course.
2. The influence of the level of postoperative activity has been inadequately studied, so no recommendations can be made (Smith et al., 2009).
3. There is level 4 evidence that medical comorbidity may have an impact on surgical outcomes, depending on the outcomes selected. There is level 3 evidence that psychological factors have an impact on subjective

and objective outcomes in different ways (Smith et al., 2005).

4. Obesity as a confounding variable is the subject of conflicting evidence in the literature and has not been studied in a prospective fashion. Obesity has been studied only retrospectively in case series as a risk factor for success or morbidity in stress incontinence surgery (level 4 evidence). **There are no prospective, randomized trials that suggest superiority of one surgical technique over another in the obese population.** Some studies have suggested increased failure rates in obese patients undergoing retropubic colposuspension (Alcalay et al., 1995; Brieger and Korda, 1992). Conversely, in a retrospective study of 198 women undergoing anti-incontinence surgery, cure rates were markedly better in those undergoing Burch colposuspension (Zivkovic et al., 1999).
5. **Surgery for recurrent stress incontinence has a lower success rate.** One study has reported that Burch colposuspension has an 81% success rate after one previous surgical procedure has failed, but this drops to 25% after two previous repairs and to 0 after three previous operations (Petrou and Frank, 2001). Other series report excellent results for colposuspension carried out after prior failed surgery. Maher et al. (1999) and Cardozo et al. (1999) have shown good objective (72% and 79%) and subjective (89% and 80%) success rates with repeated colposuspension at a mean follow-up of 9 months. In two small retrospective studies of women who underwent open and laparoscopic Burch colposuspension after failed suburethral tape procedures, the objective cure rates were 77% and 54% at a median follow-up 1 year and 24½ months, respectively (De Cuyper et al., 2008; Giarenis et al., 2012;). Nitahara et al. (1999) reported a 69% subjective success at a mean follow-up of 6.9 years.
6. Berglund et al. (1996) reported that the duration of symptoms is a predictor of outcome, with a better response in those with a shorter history, which as a finding was independent of type of approach (e.g., vaginal vs. retropubic). Ward and Hilton (2002), in a randomized comparison of colposuspension and tension-free vaginal tape (TVT), found no significant impact of symptom severity on outcomes for either procedure. Tamussino et al. (1999), in a review of 327 women assessed a minimum of 5 years postoperatively, noted that women with moderate or severe incontinence fared worse than those with milder symptoms. In

their series, only Burch colposuspension was unaffected by the severity of preoperative symptoms.

7. It has been reported that as many as 23% of women undergoing urodynamics have mixed urodynamic stress incontinence and detrusor overactivity (Clarke, 1997). In a retrospective cohort study, Colombo et al. (1996b) compared 44 women with mixed incontinence with a matched group with urodynamic stress incontinence. The cure rate was 95% in the latter group compared with 75% in the former. Other studies report a less favorable outcome of 24% to 43% in those with detrusor overactivity combined with stress incontinence (Lose et al., 1988; Milani et al., 1985; Stanton et al., 1978).
   Smith et al. (2009) concluded that **surgery for urodynamic stress incontinence should not be considered contraindicated in women with mixed symptoms of SUI and overactive bladder syndrome or mixed urodynamic findings of urodynamic stress incontinence and detrusor overactivity (grade B recommendation).** All patients undergoing surgery for SUI should be appropriately counseled to have realistic expectations of outcome; this is particularly important in those with mixed symptoms or mixed urodynamic stress incontinence (grade B recommendation).
8. The International Consultation on Incontinence (ICI), although allowing the fact that there is no consensus on the definition of intrinsic sphincter deficiency, concluded that **there are limited evidence-based data to support that intrinsic sphincter deficiency influences either the outcomes of surgery or the type of surgical treatment** (Smith et al., 2009). It would appear that a low leak point pressure is less predictive of outcome when compared with the presence or absence of urethral hypermobility (Smith et al., 2009).

Choice of Surgical Technique

Two types of stress incontinence have been suggested: one associated with a **hypermobile but otherwise healthy urethra,** a manifestation of weakened support of the proximal urethra, and one arising from a **deficiency of the urethral sphincter mechanism,** thereby compromising the ability of the urethra to act as a watertight outlet. **Hypermobility of the bladder neck and proximal urethra results from a weakening or loss of their supporting elements (ligaments, fascia, and muscles), which in turn may be a consequence of aging, hormonal changes, childbirth, and prior surgery. It seems likely that the majority of women with SUI will also have an element of intrinsic sphincteric weakness with a variable degree of loss of the normal anatomic support of the bladder neck and proximal urethra, resulting in hypermobility. An individual with normal bladder function will not have leakage regardless of how much she strains.**

Differentiating Relative Contributions of Hypermobility and Intrinsic Sphincter Deficiency

The influence of urethral function defined by leak point pressure or maximum urethral closure pressure (MUCP) is difficult to define because of the large variation in outcome measures used. Furthermore, other variables such as urethral mobility are often not controlled for. **ISD** is usually defined as a leak point pressure below 60 or MUCP below 20. A standardized test is not available to differentiate the relative contributions of ISD and hypermobility, and therefore few studies have been able to accurately separate their individual contributions to the development of incontinence (Chapple et al., 2005). **Retropubic procedures restore the bladder neck and proximal urethra to a fixed, retropubic position and are used when hypermobility is thought to be an important factor in the development of that woman's stress incontinence. This may facilitate the function of a marginally compromised intrinsic urethral sphincter mechanism, but if significant ISD is present, it is likely that SUI will persist despite efficient surgical repositioning of the bladder neck and proximal urethra;** at present this hypothesis remains unproven. In such circumstances a sling procedure (particularly a snug fascial sling) or an artificial sphincter is most likely to be the therapy of choice.

In the healthy, continent woman, the bladder neck and proximal urethra are supported in a retropubic position and the bladder base is dependent. Increases in intra-abdominal pressure are transmitted to the bladder and the proximal urethra such that the pressure difference between the two is unchanged, promoting continence (Einhorning, 1961). A valvular effect at the bladder neck created by the transmission of abdominal pressure to the dependent bladder base may also be operative here (Penson and Raz, 1996). Furthermore, with proper bladder neck support, reflex contraction of the pelvic floor muscles during Valsalva maneuvers and coughing acts as a backboard for urethral compression (Staskin et al., 1985).

Surgical Procedures

This chapter deals with retropubic surgical procedures, usually chosen as surgical therapy for patients with stress incontinence in which there is a significant component of hypermobility.

Open retropubic colposuspension is the surgical approach of lifting the tissues near the bladder neck and proximal urethra into the area of the pelvis behind the anterior pubic bones. When it is an open procedure, the approach is through an incision over the lower abdomen. There are four variations of open retropubic colposuspension: Marshall-Marchetti-Krantz (MMK), Burch, vagino-obturator shelf (VOS), and paravaginal procedures.

The term *colposuspension* was originally used to denote suspension of the urethra by the vaginal wall; however, by common usage, it now generally includes the paraurethral fascia and sometimes only this without the vagina. Retropubic colposuspension urethral repositioning can be achieved by three distinctly different procedures; these are all based on a similar underlying principle, but in a spectrum in relation to the degree of the support or elevation they achieve, and their outcomes differ somewhat in the longer term.

The **Burch colposuspension** (Fig. 123.1A) is the elevation of the anterior vaginal wall and paravesical tissues toward the iliopectineal line of the pelvic sidewall with use of two to four sutures on either side (Burch, 1961). The **VOS repair** (see Fig. 123.1B) aims to anchor the vagina to the internal obturator fascia and is a modification of a combination of the Burch and paravaginal defect repair, with placement of the sutures laterally, anchored to the internal obturator fascia rather than hitching the vagina up to the iliopectineal line

(Turner-Warwick, 1986), although a more recent modification does, where appropriate, insert stitches into the internal obturator and iliopectineal line (see Fig. 123.1C). The **paravaginal defect repair** (see Fig. 123.1D) aims to close a presumed fascial weakness laterally at the site of attachment of the pelvic fascia to the internal obturator fascia (Richardson et al., 1976). The **MMK procedure** (see Fig. 123.1E) is the suspension of the vesicourethral junction (bladder neck) toward the periosteum of the symphysis pubis (Marshall et al., 1949) and was thought to buttress the paraurethral area and bringing the vesicourethral junction into a more elevated “intra-abdominal” position.

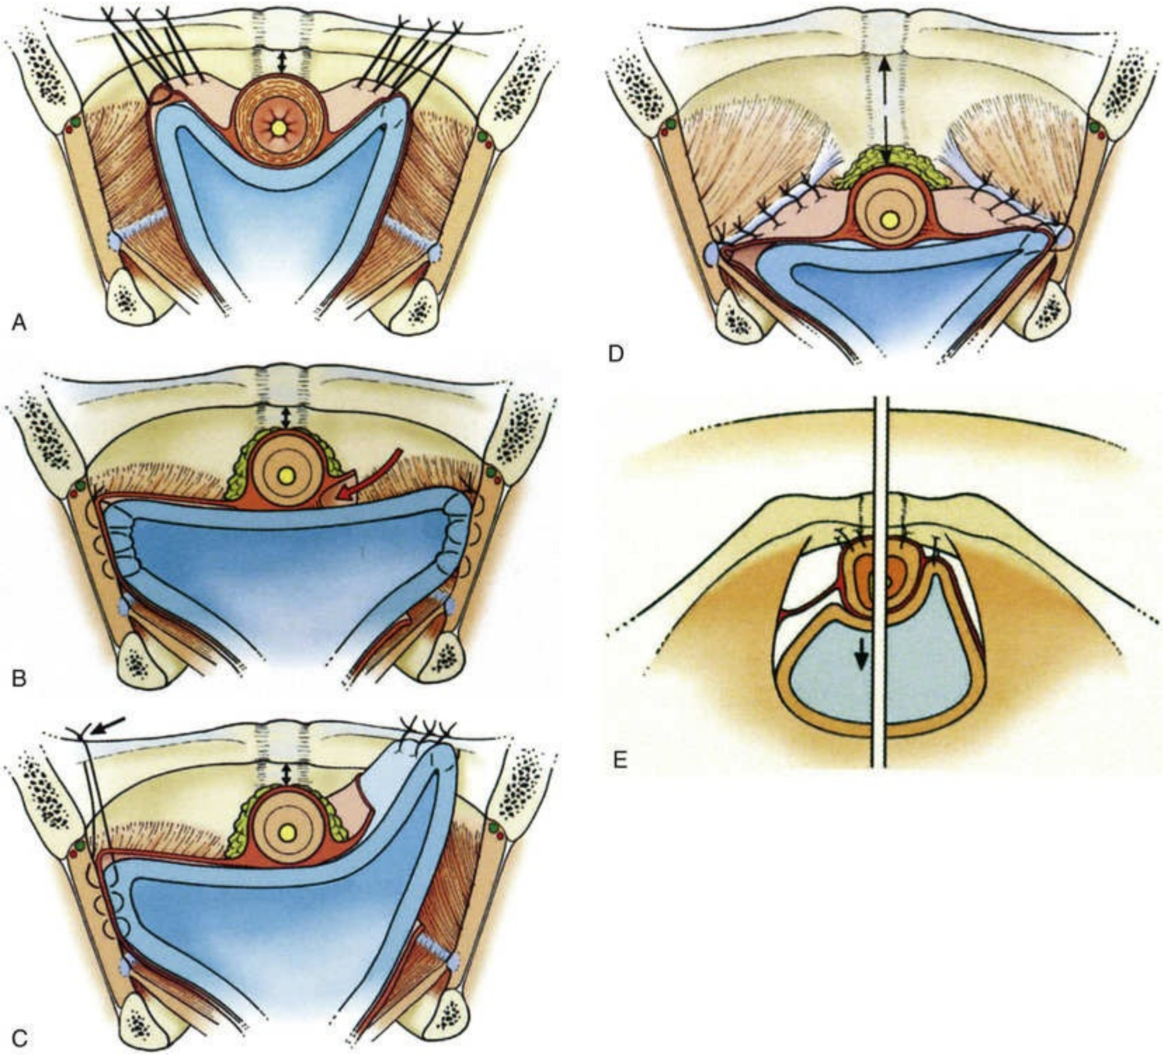

FIG. 123.1 (A) Coronal view, diagrammatic representation of a Burch colposuspension. (B) Coronal view, diagrammatic representation of a vagino-obturator shelf procedure. (C) Coronal view, diagrammatic representation of a vagino-obturator shelf procedure on the left, augmented

by stitching to the iliopectineal line, and a Burch procedure on the right. (D) Coronal view, diagrammatic representation of a paravaginal repair. (E) Diagram demonstrating the sutures in a Marshall-Marchetti-Krantz procedure and their proximity to the urethra. (From Turner-Warwick R, Chapple CR: *Functional reconstruction of the urinary tract and gynaeco-urology: an exposition of functional principles and surgical procedures,* Oxford, 2002, Blackwell Science.)

Degree of Urethral Elevation

The extent of the urethral elevation achieved by the Burch (see Fig. 123.1A) and the VOS suspensions (see Fig. 123.1B and C) is higher than the arcus tendineus anchorage of the paravaginal defect repair (see Fig. 123.1D).

Configuration of the Suspensions

A particular advantage of the horizontal urethral elevation achieved by the VOS and the paravaginal repair suspensions is the significantly lower susceptibility to tension on the urethra and to obstructive problems than with the V-shaped configuration of the Burch suspension (see Fig. 123.1A).

Tissue Approximation

The VOS and the paravaginal repair suspensions are anchored by tissue-approximating sutures; thus, unlike the Burch procedure, neither the VOS nor the paravaginal repair suspension is suture dependent in the longer term once the initial healing is complete because there is direct tissue adhesion. The VOS anchorage and suspension are significantly more robust than those of the paravaginal defect repair; the elevation this procedure achieves can be further augmented by additionally including the iliopectineal ligament in the upper sutures (see Fig. 123.1C).

Laparoscopic colposuspension is the most popular of the laparoscopic incontinence procedures that were first introduced in the early 1990s (Vancaillie and Schuessler, 1991) with the premise that, as minimally invasive procedures, they would benefit patients by avoiding the major incision of conventional open surgery and shorten the time for a return to normal activity. As in open colposuspension, sutures are inserted into the paravaginal tissues on either side of the bladder neck and then attached to the iliopectineal ligaments on the same side. However, there are technical variations in surgery with respect to the laparoscopic approach (transperitoneal into the abdominal cavity or extraperitoneal) and in the number and types of sutures, the site of anchor, and the use of mesh and staples (Jarvis et al., 1999).

Assessing Outcomes of Therapy

Before the best procedure is determined, several issues regarding outcome reporting must be addressed.

Duration of Follow-Up

Prolonged follow-up is required to assess the true benefit of an incontinence procedure. **Short-term follow-up should be considered to have begun in all studies after participants have reached 1 year of follow-up** (Abrams et al., 2002). In the short term (2 years), most procedures are successful, and success rates among procedures are similar (Leach et al., 1997). However, with longer follow-up (>5 years), failures manifest and the true benefit of the better procedures is realized. Most studies report outcomes after short-term follow-up, thus results must be interpreted with caution.

Issue of Intrinsic Sphincter Deficiency

There is no consistency in the existing literature data to support the likelihood that intrinsic sphincter deficiency can influence either the outcomes or the type of surgical treatment. The main problem is that there is no uniform consensus on the meaning of *intrinsic sphincter deficiency* and how to diagnose it (Smith et al., 2005, 2009). Nevertheless, although unsubstantiated by any unequivocal evidence, it is likely that although mild degrees of intrinsic sphincter deficiency coexist with hypermobility in most cases, in a situation in which intrinsic sphincter deficiency is the predominant problem, a repositioning procedure such as a colposuspension is less likely to be successful than a tight fascial sling or artificial sphincter.

Definition of Cure

The definition of cure varies among studies. Some authors report cure of SUI only, whereas others define cure as complete continence postoperatively, implying the absence of urgency incontinence as well. The assessment of cure may vary. Some authors report subjective cure based on patient history, questionnaire, bladder diary, or medical chart review; others use more objective measures, such as pad tests, stress tests, and urodynamics.

Finally, is the goal of complete continence reasonable, given that the condition of SUI is usually a degenerative one and corrective surgery does not replace the defective components? As well, **even in normal, healthy women, urinary continence is a spectrum of dryness; approximately 40% of nulliparous 30- to 49-year-olds experience some degree of incontinence with exercise** (Nygaard et al., 1990). It seems unreasonable to expect surgery for a degenerative condition to achieve results that are better than the nondegenerative state.

Patient's Versus the Physician's Perspective

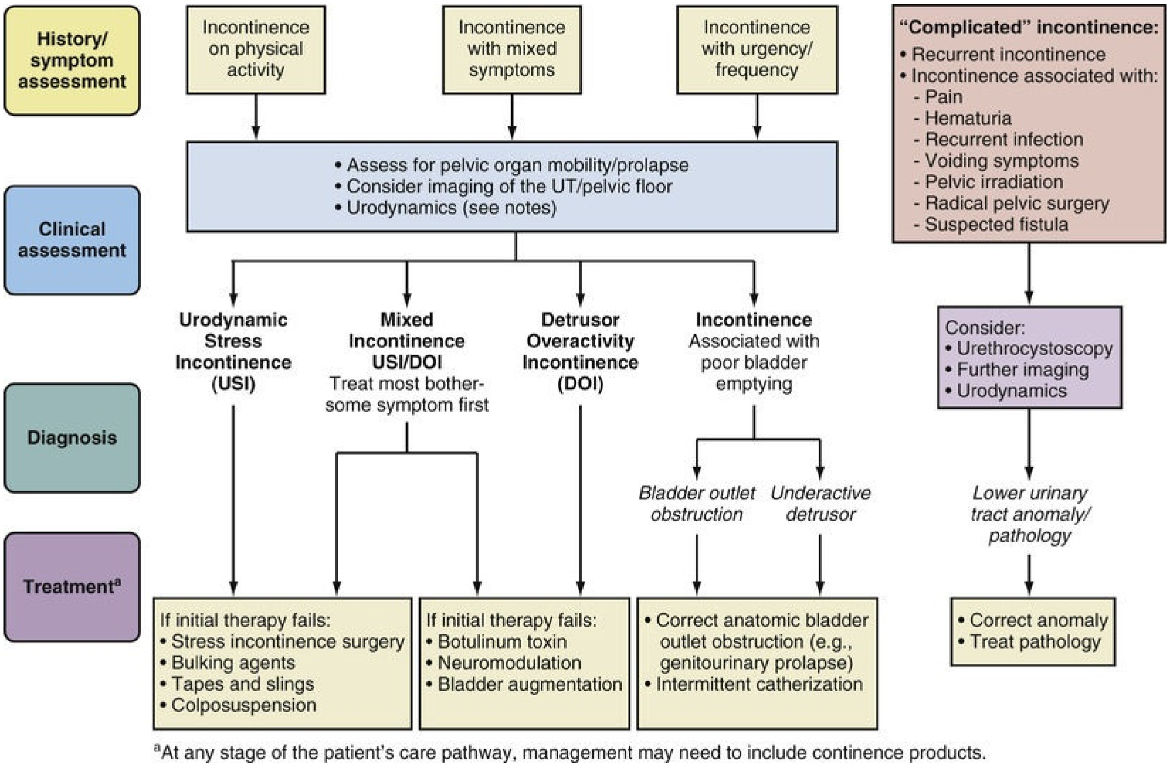
A patient's satisfaction with treatment is often based on the difference between her expectations and her experiences (Sofaer and Firminger, 2005). Thus fulfillment of positive expectations is a key element of a patient's satisfaction (Sitzia and Wood, 1997). Because expectations vary widely, satisfaction is not a standard concept. Consequently, treatment plans must be tailored to meet a nonstandard goal. An integral step in achieving this goal is the development of a patient-physician partnership that promotes the negotiation of realistic expectations.

Logically, agreement of patient and physician with respect to treatment plan and goals should improve outcomes. When a diagnosis has been made, asking patients what they already know about the condition may give clues to expectations for treatment. The “ask-tell-ask” method may be used to mend the gaps between the physician's and the patient's expectations. The physician explains the proposed treatment plan and expectations for the outcome, then encourages the patient to ask questions. The physician provides the information requested and invites questions again, continuing the process until a mutual understanding of treatments and expectations is reached (Barrier et al., 2003). This approach may prevent “surprises,” such as unexpected pain of treatment, adverse events of medication, and prolonged recovery time. Elkadry et al. (2003) emphasized this point by demonstrating a significant association between feeling unprepared for surgery and the patient's dissatisfaction after pelvic reconstruction. The same investigators also reported that achievement of patient-defined goals was more predictive of a patient's satisfaction than were objective measures of surgical success.

Clearly, one or more high-quality validated symptom and quality-of-life instruments should be chosen at the outset of a clinical trial, representing the patient's viewpoint, accurately defining baseline symptoms as well as any other areas in which treatment may be beneficial, and assessing the objective severity and subjective impact of both. **Whereas many urologists think that urodynamic studies are helpful in defining the underlying pathophysiologic process in patients with incontinence, they have not been proven to have adequate sensitivity, specificity, or predictive value** (Chapple et al., 2005)**. The ICI meeting scientific committee concluded that although urodynamic studies, such as frequency-volume charts and pad tests, are useful, there is inadequate evidence to justify pressure-flow studies for routine testing, as either entry criteria or outcome measures in clinical trials. They recommended that most large-scale clinical trials enroll subjects by carefully defined symptom-driven criteria when the treatment will be given on an empirical basis** (Abrams et al., 2002). **The committee recommended against the use of urethral function measurements of leak point pressures and urethral closure pressures as a single factor to grade the severity of urinary incontinence and therefore did not recommend the use of contemporary urethral function tests to predict the outcome of any surgical treatment for SUI** (Rovner et al., 2017)**.**

Indications for Retropubic Repair

The treatment of SUI in women must be tailored to the individual patient. Once evaluation has identified contributing factors, a trial of conservative therapy should be pursued and surgery considered for patients who do not respond to this. Careful assessment of the patient is essential in making an accurate diagnosis (Fig. 123.2).



History/ symptom assessment
Clinical assessment
Diagnosis
Treatment^a
Incontinence on physical activity
Incontinence with mixed symptoms
Incontinence with urgency/ frequency
"Complicated" incontinence:
• Recurrent incontinence
• Incontinence associated with:
- Pain
- Hematuria
- Recurrent infection
- Voiding symptoms
- Pelvic irradiation
- Radical pelvic surgery
- Suspected fistula
• Assess for pelvic organ mobility/prolapse
• Consider imaging of the UT/pelvic floor
• Urodynamics (see notes)
Urodynamic Stress Incontinence (USI)
Mixed Incontinence USI/DOI Treat most bothersome symptom first
Detrusor Overactivity Incontinence (DOI)
Incontinence Associated with poor bladder emptying
Consider:
• Urethrocystoscopy
• Further imaging
• Urodynamics
Bladder outlet obstruction
Underactive detrusor
Lower urinary tract anomaly/ pathology
If initial therapy fails:
• Stress incontinence surgery
• Bulking agents
• Tapes and slings
• Colposuspension
If initial therapy fails:
• Botulinum toxin
• Neuromodulation
• Bladder augmentation
• Correct anatomic bladder outlet obstruction (e.g., genitourinary prolapse)
• Intermittent catherization
• Correct anomaly
• Treat pathology

^{a}At any stage of the patient's care pathway, management may need to include continence products.

FIG. 123.2 Algorithm for the specialized management of stress urinary incontinence in women (after the Third International Consultation on Incontinence, Monaco, 2004). *UT,* Urinary tract.

The selection of technique is largely based on the surgeon's preference and prior experience; bladder base and urethral hypermobility may be surgically corrected by either a vaginal or a retropubic approach. Co-existing pelvic floor problems, the anatomic features of the patient, and her general health condition may also influence the choice of procedure (Lapitan et al., 2017). Although it has been suggested that a retropubic colposuspension should be considered in patients who frequently generate high intra-abdominal pressure (e.g., those with chronic cough from obstructive pulmonary disease and women in strenuous occupations) (Appell, 1993), it could also be argued that these patients may be better served by a pubovaginal sling as well.

Although SUI is now more commonly managed surgically with minimally invasive procedures, particularly with the use of mid-urethral slings, these resources and procedures are not readily available in many countries. Limitation in experience plays a role but, more importantly, this is due to the difficulty in acquiring the slings, either because of their unavailability or their prohibitive cost (Lapitan et al., 2017).

Specific Indications

A retropubic approach for the correction of anatomic SUI is indicated (1) for a patient undergoing a laparotomy for concomitant abdominal surgery that cannot be performed vaginally and (2) where there is limited vaginal access.

Potential Contraindications

If there is a history of prior failed incontinence procedures, the existence of significant sphincteric deficiency must be suspected, even if hypermobility exists, and consideration given to performing a pubovaginal sling, although retropubic colposuspension may be successful in this scenario as well (Cardozo et al., 1999; Maher et al., 1999; Nitahara et al., 1999).

When SUI exists solely because of intrinsic sphincter deficiency (i.e., a fixed, nonfunctional proximal urethra with intrinsic urethral sphincter dysfunction), a retropubic suspension procedure is less likely to be successful because there is no hypermobility to correct and the patient is better served by a pubovaginal sling, collagen injections, or artificial sphincter (Bergman et al., 1989b). Although data are limited, the ICI committee statement on urethral occlusive forces discusses two studies that showed improved outcomes among women with higher degrees of urethral hypermobility who underwent transobturator midurethral sling procedures (Rovner et al., 2017).

In cases with a pan–pelvic floor weakness, a colposuspension should not be used in isolation but should be part of a comprehensive approach to the pelvic floor and combined as appropriate with other alternative pelvic floor repair procedures. A retropubic colposuspension does not always adequately correct the associated vaginal prolapse that frequently coexists with bladder neck hypermobility. Although lateral defect cystocele and enterocele lend themselves to retropubic repair, a central defect cystocele, rectocele, and introital deficiency do not.

A retropubic colposuspension is contraindicated **when there is an inadequate vaginal length or mobility of the vaginal tissues, for example, after prior vaginal surgery, radiotherapy, or a prior vaginal incontinence procedure** (Appell, 1993). The lysis of retropubic adhesions can be performed adequately and safely by a vaginal approach in conjunction with a needle suspension procedure or pubovaginal sling.

Vaginal Versus Retropubic Surgery

From a review of the literature, there is clearly a difference in the success rate of vaginal versus retropubic surgery alone with respect to correction of stress incontinence. An **anterior colporrhaphy** can certainly be efficacious for the correction of prolapse, with reported efficacy rates in randomized controlled studies of 42% and 57% in the management of cystoceles (Sand et al., 2001; Weber et al., 2001). For the treatment of a cystocele and stress incontinence, an anterior colporrhaphy should be combined with a sling procedure. Goldberg et al. (2001), in a case-control series, demonstrated that in women with a cystocele and SUI, the addition of a pubovaginal sling to an anterior colporrhaphy significantly decreased the recurrence rate from 42% in the control group to 19% in the anterior colporrhaphy group.

A recent Cochrane review by Lapitan, Cody, and Masheyekhi (2017) reviewed the literature on randomized or quasi-randomized trials that compared open retropubic colposuspension with anterior colporrhaphy for the treatment of urinary incontinence. Evidence from seven trials evaluating a total of 695 women showed that anterior vaginal repair was less effective than open abdominal retropubic suspension on the basis of subjective cure rates with the benefit maintained over time. For anterior colporrhaphy versus open abdominal retropubic colposuspension, respectively, they found incontinence rates of 9% versus 19% (relative risk [RR] 0.46, 95% CI 0.30–0.72) before the first year of follow-up, 14% versus 36% (RR 0.37, 95% CI 0.27–0.51) at 1 to 5 years, and 28% versus 53% (RR 0.49, 95% CI 0.32–0.75) in periods beyond 5 years (Lapitan et al., 2017). Open retropubic colposuspension was also found to have more effective objective cure rates with similar results at short-term follow-up and maintained over time. Overall, the risk of failing to cure urinary incontinence through open retropubic colposuspension was only half that of anterior repair, with an estimated absolute risk reduction (ARR) of 21% (ARR 0.21, 95% CI 0.15–0.27). In addition, fewer women in the colposuspension group had repeat anti-incontinence surgery, 6.3% versus 23.4% (RR 0.11, 95% CI 0.04–0.30).

Based on data from five trials (Bergman et al., 1989a; Colombo et al., 2000, Holmes et al., 1985; Liapis et al., 1996; Quadri et al., 1999) reviewed with long-term follow-up of at least 1 year, the risk of recurrent or new prolapse was found to be more common in women who underwent open colposuspension versus anterior colporrhaphy (16% vs. 5%); however, there was significant heterogeneity across these studies, and this did not reach statistical significant when a random-effects model was used (RR 2.51, 85% CI 0.62–10.10) (Lapitan et al., 2017). Lapitan et al. (2017) concluded that **open retropubic colposuspension provides a better cure rate compared with anterior colporrhaphy alone.**

Based on the existing evidence, transvaginal sling procedures and open retropubic suspension procedures have similar success rates in the treatment of stress incontinence. However, with longer follow-up (and with the exception of the pubovaginal sling and loose mid-urethral tapes [see later in this chapter]), patients who have retropubic procedures fare better than those undergoing vaginal repairs.

Key Points: Recommendation From the International Consultation on Incontinence Committee

- Open Burch colposuspension can be recommended as an effective treatment for primary and recurrent SUI, which has longevity (Grade A recommendation) (Rovner et al., 2017).
- Anterior colporrhaphy should not be used in the management of SUI alone (Grade A recommendation) (Smith et al., 2009).

General Technical Issues

Retropubic Dissection

In open retropubic suspension procedures, good access to the retropubic space is crucial. This is best performed with the patient in the supine position with the legs abducted, in either a low or a modified dorsal lithotomy position with use of stirrups, allowing access to the vagina during the procedure and a perineal-abdominal progression. A urethral Foley catheter is inserted; the catheter balloon is used for subsequent identification of the urethra and bladder neck, and indeed, it is invaluable in allowing palpation of the edges of the bladder by appropriate manipulation. A Pfannenstiel or lower midline abdominal incision is made, separating the rectus muscles in the midline and sweeping the anterior peritoneal reflection off the bladder. It is essential to optimize the access to the retropubic space, and if a Pfannenstiel skin incision is made, it is advisable to use the suprapubic V modification described by Turner-Warwick et al. (1974). Likewise, whatever incision is made, extra valuable access to the retropubic space is obtained by extending the division of the rectus muscles down to the pubic bone and elevating the aponeurotic insertion of the rectus muscle off the upper border of the pubic bone.

The retropubic space is then developed by teasing away the retropubic fat and underlying retropubic veins from the back of the pubic bone. The bladder neck, anterior vaginal wall, and urethra are then easy to identify, often facilitated by the presence of the Foley balloon. In patients who have had previous retropubic surgery, the dissection is performed sharply, and it is important to take down all old retropubic adhesions, particularly in the case of a prior failed repair. If difficulty is encountered in the identification of the bladder neck, the bladder may be partially filled or even opened to identify its limits, and an examining finger in the vagina is invaluable in aiding the dissection (Gleason et al., 1976; Symmonds, 1972).

It is important to identify the lateral limits of the bladder as it reflects off the vaginal wall because only in this manner can the surgeon avoid inadvertent suturing of the bladder. Dissection over the bladder neck and urethra in the midline is to be avoided so as not to damage the intrinsic musculature. The lateral bladder wall may be “rolled off” medially and cephalad from the vaginal wall with a mounted swab and by use of countertraction with a finger in the vagina. It is often necessary to incise the endopelvic fascia. Occasional venous bleeding from the large vaginal veins can be controlled by suture ligation, although it often resolves with tying of elevating sutures. To aid in the identification of the lateral margin of the bladder, it is helpful to displace the balloon of the Foley catheter into the lateral recess, where it can easily be palpated through the bladder wall.

Suture Material

Absorbable sutures were used in the original descriptions of the MMK procedure (chromic catgut), Burch procedure (chromic catgut), and VOS procedure (polyglycolic acid or polydioxanone), whereas the original paravaginal repair used nonabsorbable sutures (silicon-coated Dacron). Fibrosis during subsequent healing is likely to be the most important factor in providing continued fixation of the perivaginal fascia to the suspension sites (Tanagho, 1996); nevertheless, some surgeons believe that a nonabsorbable suture material is better because of the risk of suture dissolution before the development of adequate fibrosis (Penson and Raz, 1996). Clearly, the type of suspension suture material is a personal choice, but erosion of nonabsorbent sutures into the lumen of the bladder is a not-uncommon complication and a not-uncommon source of medical litigation (Woo et al., 1995).

Bladder Drainage

Some degree of immediate postoperative voiding difficulty can be expected after retropubic suspensions (Colombo et al., 1996a; Lose et al., 1987). Immediately postoperatively, bladder drainage may take the form of a urethral or a suprapubic catheter, in general based on the surgeon's preference. A voiding trial is usually performed around the fifth day postoperatively. However, there is some evidence that a suprapubic catheter may be advantageous with respect to a lower incidence of asymptomatic and febrile urinary tract infection and earlier resumption of normal bladder function (Andersen et al., 1985; Bergman et al., 1987). In addition, the use of a suprapubic tube is usually more comfortable, allows the patient to participate in catheter management, and avoids the need for clean intermittent self-catheterization. Catheterization can be discontinued when efficient voiding has resumed, which is usually indicated by a postvoid residual (PVR) volume either less than 100 mL or less than 30% of the functional bladder volume, although no definitive evidence exists for a precise quantification of acceptable PVR.

Drains

A tube drain may be placed in the retropubic space when there is concern about ongoing bleeding from perivaginal veins that may prove difficult to control with suture and electrocautery. Often, tying the suspension sutures is sufficient to stop this bleeding, but when it persists, drainage of the retropubic space is indicated. The drain is usually removed on the first to third day, when minimal output is noted.

Marshall-Marchetti-Krantz Procedure

Technique

Marshall, Marchetti, and Krantz in 1949 described a retropubic approach for the elevation and fixation of the anterolateral aspect of the urethra to the posterior aspect of the pubic symphysis and the adjacent periosteum. Technically, the original description of the MMK procedure reported a double suture bite of the paraurethral tissue included with the vaginal wall; this may be generically entitled a cystourethropexy procedure. In 1949 Marshall et al. described their retropubic vesicourethral suspension in 50 patients; 38 of the patients had symptoms of SUI, and in 25 of those, prior gynecologic operations for urinary incontinence had failed. A simple suprapubic procedure was described by which the vesical outlet was suspended to the pubis (Marshall et al., 1949). In the original description, three pairs of sutures (taking double bites of tissue) were placed on each side of the urethra, incorporating full-thickness vaginal wall (excluding mucosa) and lateral urethral wall (excluding mucosa) (Marshall et al., 1949). Marchetti (1949) then modified the procedure to omit the tissue bite through the urethral wall because of concern about urethral injury. Apart from modifications in suture number and material over the years, the procedure remains the same today.

Cystourethropexy was often used as a secondary procedure for the resolution of persistent leaking after an anterior colporrhaphy. **A cystourethropexy procedure does not support the posterior wall of the urethra unless the sutures include the paraurethral vaginal wall, nor does it positively reduce an anterior vaginal wall prolapse in the way that the true retropubic colposuspension procedures do.** After cystourethropexy, if there is a significant urinary residual volume postcolporrhaphy with associated laxity of the anterior vaginal wall, then with the descent, this applies traction to the posterior aspect of the bladder neck and tends to “tent” it open because the anterior aspect is tethered by sutures to the back of the pubis (see Fig. 123.1E). Sutures are placed on either side of the urethra (avoiding the urethral wall), taking bites through the paraurethral fascia and anterior vaginal wall (excluding mucosa). The most proximal sutures are placed at the level of the bladder neck. Each suture is then passed into an appropriate site in the cartilaginous portion of the symphysis (Fig. 123.3). However, the main technical problem relating to the MMK procedure is the difficulty of obtaining an adequately robust anchorage of the anterior wall of the urethra and the paraurethral fascia to the symphysis and the periosteum of the pubis, where the suture bites are relatively insecure. As shown in Fig. 123.3, these sutures can potentially either distort the bladder neck and impair sphincter function (see Fig. 123.3A) or obstruct the bladder neck (see Fig. 123.3B). All sutures are inserted, and while an assistant elevates the anterior vaginal wall, each suture is individually tied, starting with the more distal pair. The proximal, or bladder neck, suture frequently must be passed through the insertion of the rectus abdominis muscle. Additional sutures may or may not be placed between the anterior bladder wall and the rectus muscles to pull the bladder farther anteriorly.

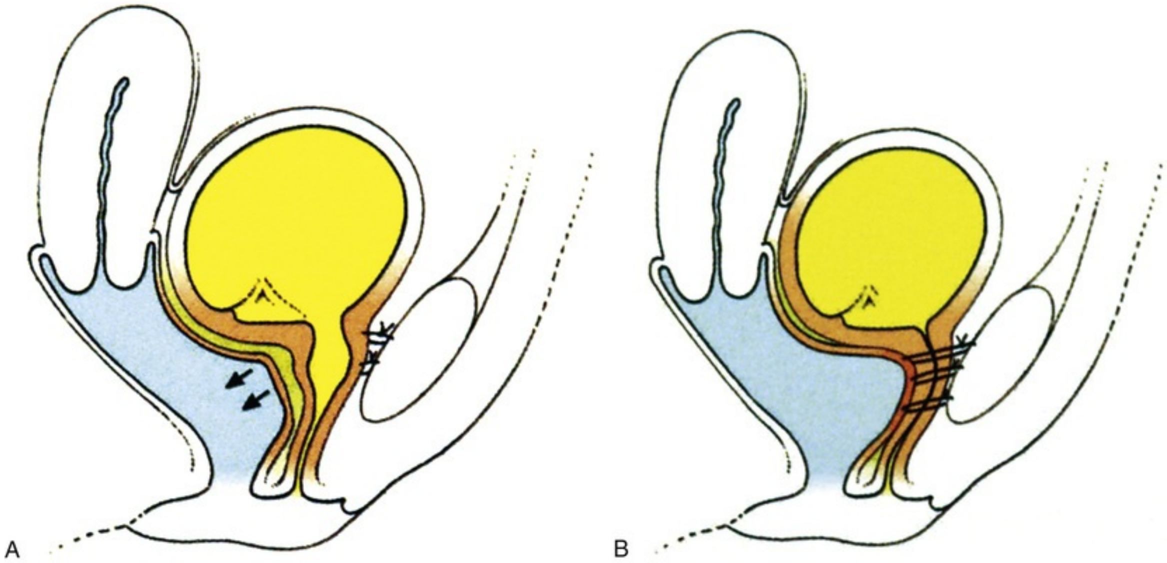


FIG. 123.3 (A) Potential risk of tethering the urethra with the Marshall-Marchetti-Krantz (MMK) procedure, influencing the function of the urethral sphincter mechanism. (B) Potential risk of obstruction of the urethra with the paraurethral sutures of the MMK procedure. (From Turner-Warwick R, Chapple CR: *Functional reconstruction of the urinary tract and gynaeco-urology: an exposition of functional principles and surgical procedures,* Oxford, 2002, Blackwell Science.)

Results

Krantz described a personal series of 3861 cases with a follow-up of up to 31 years and a 96% subjective cure rate (Smith et al., 2005). Short- and medium-term results with the MMK procedure have been good. Mainprize and Drutz

(1988) reviewed 58 articles (predominantly retrospective) published from 1951 to 1988 for treatment outcomes in 3238 cases. The cure rate, mostly based on subjective criteria, was 88%, with an improvement rate of 91%. Jarvis's meta-analysis of studies in the literature (1994b) noted subjective continence in 88.2% (range 72% to 100%) of 2460 patients with 1- to 72-month follow-up and objective continence in 89.6% (range 71% to 100%) of 384 patients with 3- to 12-month follow-up. Whether the procedure was being done primarily or secondarily affected the outcome: subjective continence in 92% if it was done primarily versus 84.5% if it was done secondarily. Longer-term data are limited in amount. McDuffie et al. (1981) reported 75% success at 15 years. More recently, Clemens et al. (1998) noted subjective cure or improvement (SUI and urgency urinary incontinence) in only 41% of patients with a mean follow-up of 17 years, and Czaplicki et al. (1998) noted decreasing continence rates from 77% at 1 year to 57% at 5 years to 28% at 10 years, with a mean duration of continence of 78½ months. There are significant limitations to the data because most series are retrospective, with preoperative assessment based mainly on history and physical examination and few studies using objective data as outcome measures.

Complications occur in up to 21% of cases (Mainprize and Drutz, 1988), and the placement of sutures through the pubic symphysis incurs the risk of osteitis pubis, a potentially devastating complication of the MMK procedure that has been reported in 0.9% to 3.2% of patients (Lee et al., 1979; Mainprize and Drutz, 1988; Zorzos and Paterson, 1996). Patients usually are seen 1 to 8 weeks postoperatively with acute pubic pain radiating to the inner thighs, aggravated by moving. Physical examination reveals tenderness over the pubic symphysis, and radiography demonstrates haziness to the borders of the pubic symphysis and possibly lytic changes. Treatment is with bed rest, analgesics, and possibly corticosteroids (Lee et al., 1979). Other specific complications of the MMK procedure have included the occasional erosion of nonabsorbable cystourethropexy sutures into the bladder lumen with stone formation. Also, the positioning of sutures in the endopelvic fascia close to the bladder neck can result in a significant outlet obstruction.

Although the MMK procedure produces a cure rate similar to that of colposuspension, the complication of osteitis pubis means that there is little to support its use as an alternative to other colposuspension procedures. Indeed, the ICI committee (Smith et al., 2009) **concluded that, although short-term results indicate comparable cure rates to colposuspension, there**

is limited evidence that the longer term outcome is poorer after MMK (evidence level 1) and declines further over time (evidence level 3). Although no new randomized controlled trials involving the MMK procedure are available, there is no evidence to support the continued use of MMK over colposuspension (Rovner et al., 2017).

Key Point: Recommendation From the International Consultation on Incontinence Committee

- The MMK procedure is not recommended for the treatment of SUI (grade A recommendation).

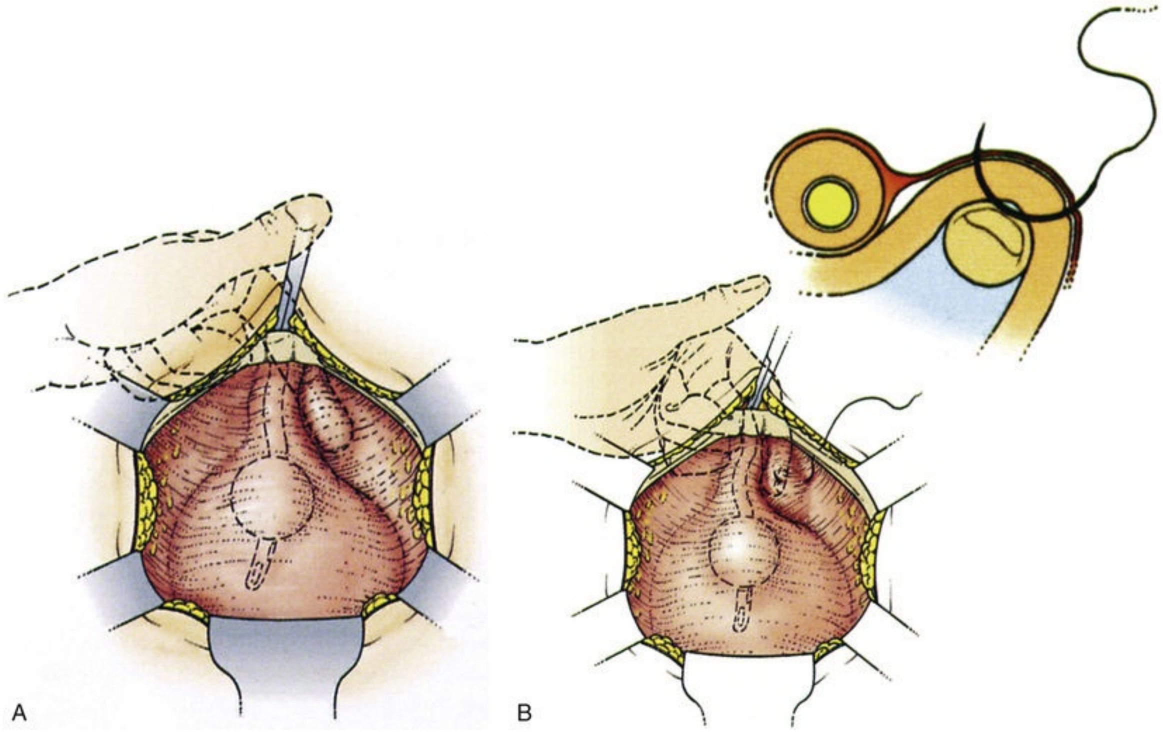
Data from Rovner E, Anathasiou S, Choo YM, et al.: Surgery for urinary incontinence in women. In Abrams P, Cardozo L, Wagg A, et al., editors: *Incontinence*, ed 6, Tokyo, Japan, 2017, pp 1741–1854.

Burch Colposuspension

Technique

Burch's original description of colposuspension in 1961 followed his original procedure, which was essentially a paravaginal repair attaching the paravaginal fascia to the white line of the pelvis, the arcus tendineus. The Burch colposuspension was a novel approach to restore the urethrovesical junction to a retropubic location by approximating the periurethral fascia to the tough bands of fibrous tissue running along the superior aspect of the pubic bone (Cooper [iliopectineal] ligament) with three pairs of sutures. The original Burch retropubic colposuspension is appropriate only if the patient has adequate vaginal mobility and capacity to allow the lateral vaginal fornixes to be elevated toward and approximated to the Cooper ligament on either side. This technique has been modified. Tanagho's modification (1978) approximated the vaginal wall to the lateral pelvic wall, with the sutures holding the anterior vaginal wall to the Cooper ligament being tied loosely so that two fingers could be placed between the symphysis and urethra. This achieved broad support for the urethra and bladder neck and potentially minimized the risk of postoperative voiding dysfunction. A more recent modification (Shull and Baden, 1989; Turner-Warwick and Chapple, 2002) involves a hybrid approach in which the vaginal tissues are approximated to the internal obturator fascia with an anchoring bite to the iliopectineal ligament (see the section on VOS repair later in this chapter).

Suture placement is facilitated by the elevation of the dissected anterolateral vaginal wall into the field by the surgeon's left vaginal-examining fingers (Fig. 123.4). The bladder is retracted to the opposite side with a mounted swab. Two to four sutures are placed on each side, each suture taking a good bite of fascia and vaginal wall, with care taken not to pass through the vaginal mucosa. Some recommend taking double bites of tissue to lessen the risk of suture pull-through (Jarvis, 1994a). The most distal suture is at the level of the bladder neck and placed no closer than 2 cm lateral to it, although some place distal sutures at the mid-urethral level (Tanagho, 1978). The suspension suture bites of the paraurethral fascia should not be positioned too close to the bladder neck and the urethra, as they are in the cystourethropexy procedures (MMK), because the unwanted effect of lateral traction-tension created by their anchorage to the iliopectineal ligaments may increase the sphincteric occlusive effect on the urethra or create a degree of obstructed voiding. Subsequent sutures are placed proximal to the level of the bladder neck, at about 1-cm intervals. The sutures are then placed into corresponding sites in the Cooper ligament, the emphasis being on a mediolateral direction for the sutures. The exact mechanism of continence of the Burch procedure is still unknown. Burch (1968) thought it to be secondary to elevation and stabilization of the bladder neck and urethra. In support of the suggestion regarding suture placement, Digesu et al. (2004) reviewed magnetic resonance imaging (MRI) findings before and 1 year after open Burch colposuspension (OBC) in 28 women to see if this would explain the mechanism. In the 86% who were cured, the distance between the levator ani muscle and bladder neck was significantly shorter than in those in whom treatment failed. Digesu's suggestion is that insertion of sutures in a medial-lateral direction as opposed to an anterior-posterior direction may better appose the levator ani muscle and bladder neck. The highly vascular vaginal wall may bleed profusely during suture placement, and large vaginal veins often must be oversewn, but most bleeding ceases once the sutures are tied and the vagina is suspended. To facilitate tying of the sutures, the assistant elevates the appropriate portion of the vaginal wall as each suture is tied, commencing with the more distant pair.



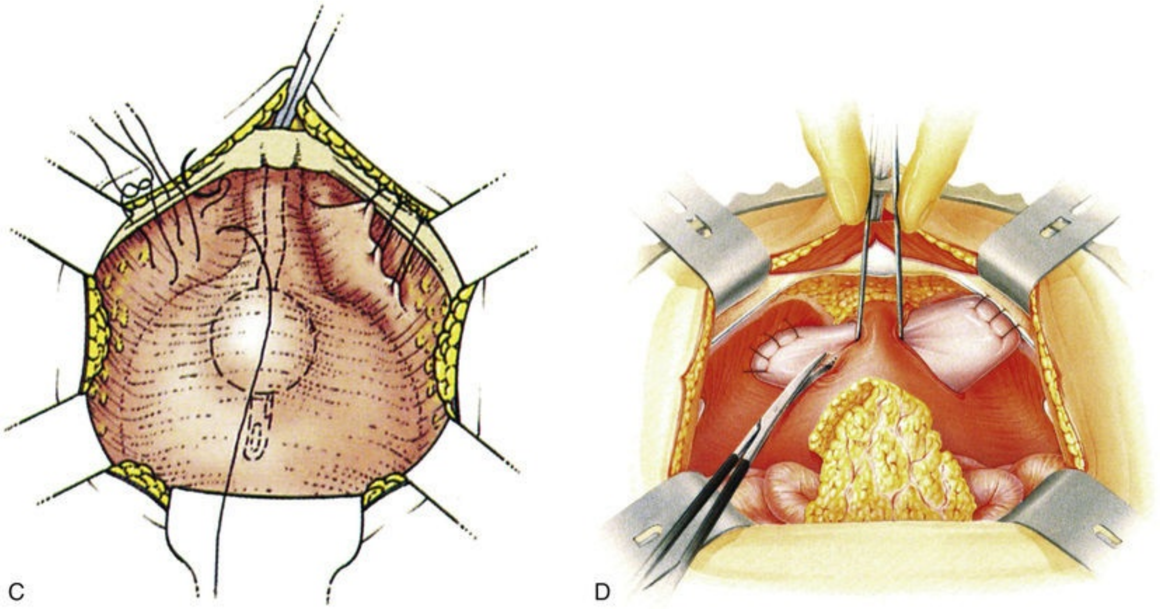


FIG. 123.4 (A) The use of a finger in the vagina when the pelvic tissues are dissected superomedially off the vagina. (B) Medial suture placement; note the role of the finger in steering the suture *(inset)*. (C) Note the mediolateral orientation of the sutures. (D) Completion of a retropubic colposuspension with a vagino-obturator hitch on the left and a Burch procedure on the right. (From Turner-Warwick R, Chapple CR: *Functional reconstruction of the urinary tract and gynaeco-urology: an exposition of functional principles and surgical procedures,* Oxford, 2002, Blackwell Science.)

No attempt should be made to tie the sutures tightly. Often the vaginal wall does not approximate to the Cooper ligaments, and free suture material is seen between the vagina and the ligaments. The principle is to approximate the vaginal wall to the lateral pelvic wall, where it will heal and promote adhesion formation (Shull and Baden, 1989; Tanagho, 1978; Turner-Warwick and Chapple, 2002)**, thereby creating a broad support for the urethra and bladder neck.**

Results

As in the MMK procedure, short- and medium-term outcomes with the Burch procedure have been good. In Jarvis's meta-analysis (1994b), subjective continence was achieved in 91% (range 63% to 97%) of more than 1300 patients with 3 to 72 months of follow-up and objective continence in 84% of more than 1700 patients with 1 to 60 months of follow-up. Lapitan et al. (2003) reviewed 33 trials involving a total of 2403 women who underwent open colposuspension and found an overall cure rate of 68.9% to 88.0%, with a 1-year cure rate of approximately 85% to 90%. This decreased to 70% at 5 years. Although there may be a decline in the cure rate of only 15% to 20% beyond 5 years, Alcalay et al. (1995) noted a subjective and objective SUI cure rate of 69% with a mean follow-up of 13.8 years. Baessler and Stanton (2004) examined the impact of surgery on coital incontinence. Of the 30 women available for postoperative evaluation, 73% preoperatively had incontinence with penetration, 10% with orgasm only, and 17% with both. Postoperatively, 70% were cured of their coital incontinence. Moreover, in those who were subjectively cured of their stress incontinence, 87% were also cured of their coital incontinence.

Lapitan, Cody, and Mashayekhi (2017) updated the Cochrane Collaboration review on open retropubic colposuspension for urinary incontinence in women. They reviewed 55 trials, including a total of 5417 women, and noted that the overall cure rate was 68.9% to 88.0% for open retropubic colposuspension. Two small studies suggested lower continence rates compared with conservative treatment; one trial suggested lower continence rates after open retropubic colposuspension compared with anticholinergic treatment. The evidence accrued from 6 trials showed a lower incontinence rate after open retropubic colposuspension than after anterior colporrhaphy, with these benefits being maintained over time. Evidence was obtained from 22 trials in comparison of open retropubic colposuspension with suburethral slings (traditional slings or trans-vaginal tape or transobturator tape) and found no significant differences in incontinence rates in all time periods assessed. However, subgroup analysis of studies comparing traditional slings and open colposuspension showed better effectiveness with traditional slings in the medium and long term. In comparison with needle suspension, there was a lower incontinence rate after colposuspension in the first year after surgery (RR 0.66, 95% CI 0.42–1.03), after the first year (RR 0.56, 95% CI 0.39–0.81), and beyond 5 years (RR 0.32, 95% CI 15–0.71). The patient-reported continence rates at short-, medium-, and long-term follow-up showed no significant difference between open and laparoscopic retropubic colposuspension, but with wide confidence intervals. In two trials, incontinence was less common after Burch colposuspension than after the MMK procedure at 1- to 5-year follow-up. There were few data at any other follow-up time. The general finding was that the evidence did not show a higher morbidity or complication rate with open retropubic colposuspension compared with the other open surgical techniques, although pelvic organ prolapse (POP) was more common than after anterior colporrhaphy and sling procedures. The authors concluded that **open retropubic colposuspension is an effective treatment modality for SUI, especially in the long term.** Within the first year of treatment the overall continence rate is approximately 85% to 90%. After 5 years approximately 70% of patients can expect to be dry. Laparoscopic colposuspension should allow speedier recovery, but its relative safety and long-term efficacy remain to be established (Lapitan et al., 2017).

Unlike with the MMK procedure, the good results with the Burch procedure appear to be durable with longer follow-up. Lapitan et al. (2003) **reached the conclusion from a review of two trials comparing the Burch colposuspension and the MMK procedure that the Burch technique results in higher cure rates. Thus it should be regarded as the *standard* open retropubic colposuspension procedure.**

Open colposuspension is as effective as any other procedure in primary or secondary surgery at curing SUI with proven long-term success (level 1 evidence, grade A recommendation) (Smith et al., 2005).

Prophylactic Colposuspension

In 2006 the Colpopexy and Urinary Reduction Efforts (CARE) trial demonstrated that the **postoperative risk of stress incontinence in stress continent women undergoing open abdominal sacrocolpopexy could be substantially reduced by the addition of a Burch colposuspension** (Brubaker et al., 2006). Initial results at 3 months postprocedure demonstrated reduction of de novo stress incontinence from 44% in the untreated group to 24% in the Burch group, without increased rates of voiding dysfunction or urgency symptoms. Subsequent 1- and 2-year outcomes from the CARE trial showed continued benefit in patients who received the concomitant Burch procedure (Brubaker et al., 2008; Burgio et al., 2007).

Costantini et al. (2012) reported on POP repair with and without concomitant Burch colposuspension in incontinent women in an RCT with at least 5 years' follow-up. This study was an update of a previously published trial on the impact of Burch colposuspension as an anti-incontinence procedure in patients with urinary incontinence and POP. Forty-seven women were randomly assigned to abdominal POP surgery and concomitant Burch colposuspension (24 patients) or POP surgery alone without any anti-incontinence surgery (23 patients). The median follow-up was 82 months (range 60 to 107). From 47 patients, 30 reached 6-year follow-up and 2 patients were lost to follow-up. In the first group, undergoing both POP and Burch colposuspension, 2 patients showed a stage 1 rectocele. In the second group, 2 patients had a stage 1 rectocele and 1 a stage 2 rectocele. In the first group, 13 out of 23 were still incontinent after surgery (56.5%) compared with 9 out of 22 (40.9%) of those who underwent only prolapse surgery. There was no significant change over time from the original assessment of this group. The authors concluded that Burch colposuspension did not improve outcomes significantly in incontinent patients when they were undergoing POP repair.

Reoperative Surgery

Poorer results are likely to occur when the procedure is performed secondarily. Scarring and fibrosis from previous surgery can prevent adequate suspension in some cases, and suture cut-through is more likely. Furthermore, after failed surgery, patients may have coexisting sphincteric weakness that places them at greater risk of recurrence after colposuspension (Bowen et al., 1989; Koonings et al., 1990).

Nevertheless, Maher et al. (1999) and Cardozo et al. (1999) have shown good objective (72% and 79%) and subjective (89% and 80%) success with repeated colposuspension at a mean follow-up of 9 months. Nitahara et al. (1999) reported 69% subjective success at a mean follow-up of 6.9 years. Urgency incontinence and sphincteric weakness are the main causes of failure and dissatisfaction. Urgency incontinence accounted for 63% (12 of 19) of failures; the remaining 7 with persistent stress incontinence in Nitahara's series demonstrated sphincteric deficiency with mean Valsalva leak point pressures of 65 cm H_2O. The low-pressure urethra has often been quoted to be an adverse risk factor for colposuspension (Bowen et al., 1989; Haab et al., 1996; Koonings et al., 1990), but this topic also remains controversial. Several authors have studied the urethral pressure profilometry changes after colposuspension and have noted a statistically significant increase in the postoperative pressure transmission ratio but minimal changes in the postoperative MUCP, functional urethral length, and continence area (Faysal et al., 1981; Feyersiel et al., 1994; Weil et al., 1984). Although a low-pressure urethra (MUCP <20 cm H_2O) is considered a contraindication to the Burch procedure, a modification of the standard Burch operation has had some success in managing SUI associated with the low-pressure urethra. Bergman et al. (1989c) combined a standard Burch procedure with the Ball procedure (Ball, 1963), wherein before the Cooper ligament suspension is performed, two or three sutures are used to plicate the anterior urethral wall at the level of the proximal and middle urethra. These researchers retrospectively noted greater success with this technique than with a standard Burch procedure for the low-pressure urethra, and this was comparable to the success obtained with a standard Burch procedure in patients with a normal-pressure urethra (MUCP >20 cm H_2O). With longer follow-up, the Ball-Burch procedure continued to yield better results than the standard Burch procedure in patients with a low-pressure urethra, with a documented 5-year cure rate of SUI of 84% (Bergman et al., 1991; Elia and Bergman, 1995). However, there are no randomized studies addressing the issue, and whether these results can be extrapolated for the use of this technique in patients with intrinsic sphincter deficiency is debatable.

Giarenis et al. (2012) pose the question of what to do when a mid-urethral tape fails, emphasizing the potential role of open colposuspension as a salvage continence procedure. This was a retrospective study of 13 women who had undergone open colposuspension after a failed mid-urethral sling. The average time between insertion of the mid-urethral tape and the colposuspension was 22.6 (range 8 to 72) months. The mean operating time was 77 (range 43 to 123) minutes, including the time for the concomitant surgery. The mid-urethral tape was identified and partially excised. The authors reported a median follow-up of 12 months. Subjective and objective cure rates were 85% and 77%, respectively. Only 1 woman had severe SUI postoperatively, requiring further surgery. Three of the 8 women with preexisting urinary urgency reported postoperative improvement. Two patients reported de novo urinary urgency and urgency incontinence. Three of 10 women developed de novo detrusor overactivity that responded to anticholinergic medication. Long-term voiding difficulty was observed in only 1 patient, who performed clean intermittent catheterization for 3 months. No patients developed recurrent urinary incontinence. Three women (23%) developed symptomatic prolapse postoperatively. These patients were at stage II on the Pelvic Organ Prolapse-Quantification (POP-Q) System scale involving the posterior vaginal compartment and underwent posterior repair within 22 months of colposuspension. Bearing in mind that this is a small series, nevertheless it raises the point that, allowing for the fact that there is morbidity associated with a colposuspension in this context, it is still a potential therapeutic option in these patients.

A recent Cochrane meta-analysis has looked at the evidence for the treatment of recurrent SUI after failed minimally invasive synthetic suburethral tape surgery in women (Bakali et al., 2013). Twelve studies were identified, but all were excluded because they did not meet the eligibility criteria. Six were RCTs but were not eligible because the previous incontinence surgery had not been a suburethral tape. A subset of one RCT may have been eligible for inclusion because one of the women was having repeat surgery, but the authors were unable to obtain the data according to primary surgery for this cohort from the authors of the original study. The question of how to best deal with recurrent stress incontinence after a tape procedure will depend on whether the primary problem is that of intrinsic sphincter deficiency or problems with repositioning the urethra, and the question as to whether colposuspension may have a role in this context still remains open on the basis of this review of the literature because there is no clear evidence-based conclusion available.

Conversely, Shao et al. (2011) reported on TVT retropubic sling for recurrent SUI after Burch colposuspension failure. In this small series of 24 women undergoing TVT procedures for recurrent stress incontinence after a previous failed Burch colposuspension, the median follow-up was 57 months (range 12 to 96 months). Preoperative and postoperative urethral mobility and urodynamics were evaluated. It was noted that preoperatively in all women there was intrinsic sphincter deficiency, and 14 had urethral hypermobility. Postoperatively, 15 patients were completely dry, and 2 had a leakage of urine less than 5 g/h. The overall success rate was 70.8%, and there was a significant postoperative increase of MUCP and a decrease of average flow rates and average hypermobility. The authors concluded that recurrent SUI after a Burch colposuspension can be successfully treated with a TVT procedure. This, however, must be considered cautiously as a conclusion, because in the context of intrinsic sphincter deficiency, many authors in contemporary practice would express concern about putting in such a sling under any degree of tension to correct intrinsic sphincter deficiency because of the long-term potential complications with sling exposure that may occur. In this context, the potential use of an autologous sling should be carefully considered.

As with any major abdominal or pelvic surgical procedure, intraoperative and perioperative complications that may occur after a retropubic suspension include bleeding, injury to genitourinary organs (bladder, urethra, ureter), pulmonary atelectasis and infection, wound infection or dehiscence, abscess formation, and venous thrombosis or embolism. Other complications more specific to retropubic suspension procedures include postoperative voiding difficulty, detrusor overactivity, and vaginal prolapse. These are discussed in more detail along with other reported complications in a later section in this chapter.

Key Points: Recommendations From the International Consultation on Incontinence Committee

- Open Burch retropubic colposuspension can be recommended as an effective treatment for primary and recurrent SUI, which has longevity (grade A recommendation).
- Although open colposuspension has, to a large extent, been superseded by the less invasive mid-urethral tapes, it should still be considered for those women in whom an open abdominal procedure is required concurrently with surgery for SUI (grade D recommendation).

Data from Rovner E, Anathasiou S, Choo YM, et al.: Surgery for urinary incontinence in women. In Abrams P, Cardozo L, Wagg A, et al., editors: *Incontinence*, ed 6, Tokyo, Japan, 2017, pp 1741–1854.

Paravaginal Repair

Technique

The origins of the paravaginal repair date to White (1912, 1997), who described the importance of the “white line” of the pelvis (arcus tendineus) as an integral structure supporting the proximal urethra and bladder base to the pelvic wall and the development of paravaginal fascial tears predisposing to cystocele formation. He performed the paravaginal repair by a vaginal approach but envisioned that it would be easier if performed abdominally (White, 1912). Later, in his original description, Burch attached the vaginal wall to the arcus tendineus in seven patients, only to realize that the attachment may not be secure, prompting him to use the Cooper ligament as an attachment site (Burch, 1961). In the 1970s, Richardson et al. (1976) reintroduced the concept of a lateral defect cystourethrocele as a causative factor in the genesis of SUI and popularized the paravaginal repair as a technique for management.

The patient is placed in a low lithotomy position, just as for the MMK procedure and Burch colposuspension. If there are retropubic adhesions resulting from prior surgery, they are sharply incised; the dissection is facilitated by placement of two fingers of the surgeon's left hand in the vagina. The bladder and urethra are not mobilized from the vaginal attachments. Richardson et al. (1981) describe an extensive reattachment of the lateral vaginal sulcus with its overlying fascia to the arcus tendineus fasciae pelvis from the back of the lower edge of the symphysis pubis to the ischial spine, using six to eight sutures placed at 1-cm intervals. The vaginal wall in the region of the bladder neck is identified, and these interrupted sutures are placed at approximately 1-cm intervals through the paravaginal fascia and vaginal wall (excluding vaginal mucosa) beginning at the urethrovesical junction. The sutures are then passed through the adjacent obturator fascia and underlying muscle at the site of the arcus tendineus fascia (Fig. 123.5). If the arcus is not visible, the obturator foramen may be used as a landmark. It is situated 1.5 to 2 cm above the white line.

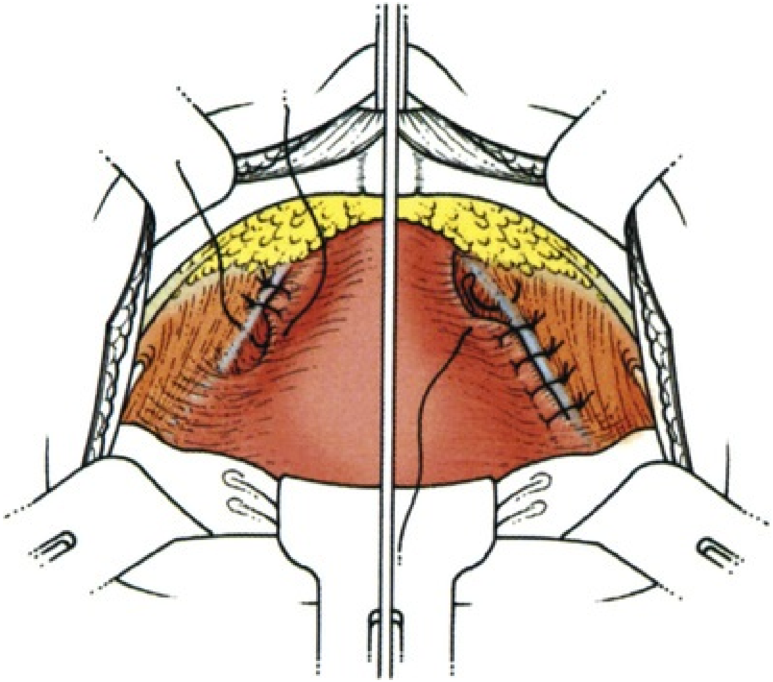

FIG. 123.5 A paravaginal repair procedure.

The end point that should be achieved is the reestablishment of the urethral axis in an anatomic position, easily allowing three fingerbreadths between the pubic symphysis and the proximal urethra but providing secure fixation and preventing rotational descent. Consequently, it has been reported that postoperative voiding difficulties are uncommon (Richardson et al., 1981).

Results

Few reports on the use of this technique have been published. With variable follow-up, cure rates greater than 90% have been reported for the paravaginal repair (Richardson et al., 1981; Shull and Baden, 1989). There is only a single randomized comparison of colposuspension with paravaginal repair including 36 patients who were randomly allocated to treatment by either colposuspension or paravaginal repair with nonabsorbable suture material. At 6 months of follow-up, there was an objective cure rate of 100% for those undergoing colposuspension and 72% for those undergoing paravaginal repair (Colombo et al., 1996a).

Small series have reported on vaginal approach to paravaginal repairs (Mallipeddi et al., 2001; Scotti et al., 1998). In particular, Mallipeddi et al. followed 45 patients (21 with SUI) after this approach for a mean of 1.6 years, and 57% had persistent stress incontinence; the conclusion of these researchers was that this technique had limited applicability for SUI. **It can be concluded that there is level 1 or 2 evidence that abdominal paravaginal repair is less effective than colposuspension. There are limited data (level 3 or 4) on laparoscopic and vaginal paravaginal repairs, but interpretation of these data is hampered by the small numbers of patients, the short follow-up, and a combination of this procedure with other types of incontinence procedures** (Smith et al., 2005).

There is limited evidence that abdominal paravaginal defect repair is less effective than open colposuspension (evidence level 2) (Smith et al., 2009).

Key Point: Recommendation From the International Consultation on Incontinence Committee

- Paravaginal defect repair is not recommended for the treatment of SUI alone (grade A recommendation).

Data from Smith AR, Chang D, Dmochowski R, et al.: Committee 14. Surgery for urinary incontinence in women. In Abrams P, Cardozo L, Khoury S, et al., editors: *Incontinence*, Plymouth, UK, 2009, Health Publications, pp 1191–1272.

Vagino-Obturator Shelf Repair

Technique

Turner-Warwick (1986; Turner-Warwick and Chapple, 2002) reported his variant of the paravaginal repair, which he called the *vagino-obturator shelf repair.* The premise for this is that there should be no restriction to the intrinsic sphincteric function of the urethra by fixation or paraurethral tethering, and there should be no urethral compression (Turner-Warwick and Kirby, 1993).

Just as for other retropubic suspension procedures (Fig. 123.6), the anterior wall of the lower segment of the bladder wall is exposed and the position of the bladder neck is identified by gentle traction on a balloon catheter in the urethra. The surgeon's forefinger in the vagina elevates its anterior wall and the overlying endopelvic fascia on either side of the urethra. Lateral displacement of the catheter balloon with the finger in the vagina facilitates the identification of the inferolateral margin of the bladder, lateral to the bladder neck, and its separation from the paraurethral endopelvic fascia is achieved by simple blunt dissection with a sponge or scissor-tip retraction. This naturally exposes the surface of the obturator muscle and the arcus tendineus origin of the levator muscles deep in the sulcus below this, the site of suture placement in the paravaginal repair (which is well below the vaginal anchorage point in the VOS procedure). The obturator nerves lie superolaterally; their canals run high up in a groove under the superior pubic ramus so that once they have been identified, injury to them can be avoided. The full thickness of the vagina and its overlying layer of endopelvic fascia are elevated by the surgeon's finger in the vagina and are approximated to the internal obturator muscle and anchored to the bulk of this with absorbable 0 or No. 1 sutures mounted on robust 35- to 40-mm half-circle needles. Slight flexion of the fingertip tents the vaginal wall and facilitates the full-thickness insertion of these suture bites through it, thus avoiding inclusion of the surgical glove. Three or four successive sutures are inserted. For knot security, these are best tied continuously, head to tail, as they are inserted, rather than separating them individually. Each tied suture bite facilitates the insertion of the next (unlike in the Burch procedure, in which the sutures are not tied until they have all been inserted). A similar obturator suspension of the elevated protrusion of the vagina and its overlying endopelvic fascia is achieved on the opposite side. Some additional elevation of the lateral anchorage of the VOS by the inclusion of a bite of the iliopectineal ligament within the suture bite approximating the vagina to the obturator muscle (as in a Burch procedure) may be used to reinforce the repair (Shull and Baden, 1989). This modification represents a hybrid with the Burch procedure, facilitating reattachment of the pubocervical fascia to the arcus tendineus fasciae pelvis, tissue apposition to the lateral pelvic wall, and nonobstructive elevation of the urethra and urethrovesical junction. In addition, obliteration of the pouch of Douglas (culdoplasty) may be needed to prevent enterocele (Shull and Baden, 1989; Turner-Warwick and Kirby, 1993).

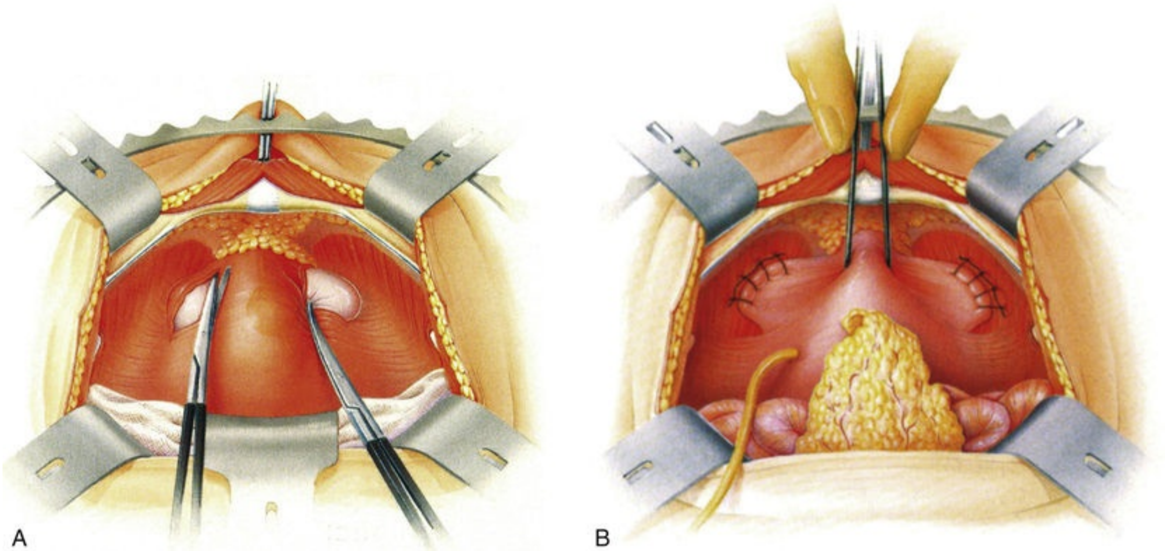

FIG. 123.6 (A) Mobilizing the tissues. The tissues should be stripped by blunt dissection with a mounted swab or the edge of a pair of scissors; only occasionally is sharp dissection necessary, provided the stripping action starts far laterally adjacent to the pubic bone. (B) Completed vagino-obturator shelf procedure. (From Turner-Warwick R, Chapple CR: *Functional reconstruction of the urinary tract and gynaeco-urology: an exposition of functional principles and surgical procedures,* Oxford, 2002, Blackwell Science.)

Results

There are limited data available for the VOS repair, which has had reported cure rates of 60% to 86%, depending on whether the procedure was performed primarily or secondarily (German et al., 1994; Turner-Warwick, 1986). German et al. (1994) reported that the VOS procedure is less likely to be successful in patients who have undergone previous surgery.

Ultimately, as with all such reconstructive surgery, the surgeon should select the correct procedure for the individual patient. Although the VOS, which is a synthesis of the principles of the paravaginal repair and the Burch colposuspension, is of interest, further clinical results are necessary before definitive conclusions can be drawn.

Laparoscopic Retropubic Suspension

Laparoscopic techniques for retropubic suspension were introduced by Vancaillie and Schuessler in 1991. They essentially performed an MMK urethropexy laparoscopically, and since that time, laparoscopic techniques have been applied to the Burch procedure and the paravaginal repair. Subsequent modifications to the suspension suturing techniques have been introduced, including the use of mesh (Ou et al., 1993), staples (Lyons, 1994), and fibrin sealant (Kiilholma et al., 1995), but all adhere to the same principles of their open counterparts. Proposed advantages of the laparoscopic approach include improved intraoperative visualization, less postoperative pain, shorter hospitalization, and quicker recovery times (Liu, 1993). Disadvantages include greater technical difficulty with resultant longer operating times and higher operating costs (Paraiso et al., 1999).

The procedure may be performed extraperitoneally or transperitoneally, and each approach has its proponents. Although the extraperitoneal technique may be associated with shorter operating times, easier dissection, and fewer bladder injuries (Frankel and Kantipong, 1993; Raboy et al., 1995), the transperitoneal approach provides a larger operating space and the ability to perform concomitant intraperitoneal procedures and apical prolapse repair (Paraiso et al., 1999). The specifics of the different procedures are beyond the scope of this chapter.

Short- and medium-term outcomes with the laparoscopic retropubic suspensions have become available. In their review of 13 studies of laparoscopic retropubic suspensions, Paraiso et al. (1999) found cure rates to range from 69% to 100% with follow-up of 1 to 36 months. This is comparable to outcomes of the open procedures as already noted. Retrospective (Polascik et al., 1995) and randomized, prospective comparisons (Summitt et al, 2000) between open and laparoscopic techniques have demonstrated similar short-term success. However, with longer follow-up, laparoscopic retropubic suspensions appear to fail more frequently. McDougall's group (1999) retrospectively noted only 30% cure of SUI and 50% cure or improvement after a laparoscopic Burch procedure with 45 months of follow-up, and this was no different from the results with a Raz procedure.

A recent Cochrane review updated by Dean et al. (2017) identified 22 eligible studies, 10 of which compared laparoscopic with open colposuspension, to determine the effects of laparoscopic colposuspension for urinary incontinence in women. All of these trials had varying lengths of follow-up ranging from 6 months to 5 years. In addition, the number or type of mesh or sutures used was not consistent across the studies. Burton (1997) used absorbable Dexon sutures, whereas six trials used nonabsorbable sutures, mainly Ethibond (Ankardal et al., 2004; Ankardal et al., 2005; Cheon et al., 2003; Kitchener et al., 2006; Su et al., 1997; Summitt et al., 2000) or polypropylene sutures (Fatthy et al., 2001). All of the studies except for two (Ankardal et al., 2004; Su et al., 1997) used the same number and type of suspension material for the laparoscopic and open procedures. Ankardal et al. (2004) used a polypropylene mesh and Titan staples for the laparoscopic colposuspensions and sutures for the open colposuspensions. According to unpublished data, Su et al. (1997) revealed methodologic problems with corrupted randomization and confounding factors of performance of additional surgery in some patients and the use of a different number of sutures on paravaginal fascia for laparoscopic (one suture) and open (three sutures) colposuspension. In three of the studies (Burton, 1997; Cheon et al., 2003; Fatthy et al., 2001), surgeons had performed fewer than 20 laparoscopic colposuspensions before starting the trial. Other studies either reported surgeons as being senior gynecologists with extensive experience in both procedures (Ankardal et al., 2004, 2005; Carey et al., 2000; Kitchener et al., 2006; Su et al., 1997) or did not report the experience of the surgeons (Morris et al., 2001; Summitt et al., 2000). The ability to synthesize data was also limited by the variable tests and definitions used to measure subjective and objective outcomes across the trials and failure to report standard definitions (Dean et al., 2017).

In their review, Dean et al. (2017), found subjective cure rates ranged from 58% to 96% in the open colposuspension and 62% to 100% in the laparoscopic colposuspension group within 18 months of follow-up (RR 0.95, 95% CI 0.90–1.00). The authors also re-ran an analysis after excluding the study by Su et al. (1997) because of concerns noted earlier and found that this did not change the results. The results from Burton (1997) were not included in these analyses because of the way they had presented their data. In this trial, based on visual analog scales of “cure,” the open group had better results and increasingly so at 3 and 5 years. This finding should be interpreted cautiously, however, because there are concerns that the surgeon's laparoscopic performance may have been suboptimal because he had performed few laparoscopic colposuspensions when the trial started. Kitchener et al. (2006) reported subjective cure rates at 2 years, and there were no differences between the laparoscopic and open groups (RR 1.00, 95% CI 0.81–1.25). Morris et al. (2001) reported data from 5 to 7 years of follow-up showing that the laparoscopic colposuspension group had a significantly higher subjective cure rate than the open colposuspension group (RR 1.53, 95% CI 1.00–2.35), which is contrary to the findings by Burton (1997).

Dean et al. (2017) identified two studies that used urinary diaries and pad tests to quantify symptoms on follow-up (Burton, 1997; Fatthy et al., 2001). Both groups in the Burton study (1997) improved significantly after surgery. However, this was less so in the laparoscopic group and there was a marked deterioration over time such that by 5 years' follow-up the mean number of incontinent episodes in the laparoscopic group was approaching the preoperative level. On the contrary, Fatthy et al. (2001) found no apparent difference between the groups in incontinent episodes at 18 months.

All 10 studies identified by Dean et al. (2017) assessed leakage on a clinical stress test and reported data as objective cure rates. Objective cure was defined by negative urodynamic testing in 6 studies and by negative pad test in 4 studies. Overall, the objective cure rate within 18 months showed a statistically significant reduction of risk ratio in laparoscopic colposuspension, thus favoring open colposuspension (RR 0.91, 95% CI 0.86 –0.96). There was no significant difference between laparoscopic and open colposuspension groups in objective cure rates between 18 months and 5 years (RR 1.01, 95% CI 0.88–1.16). In addition, there was no statistically significant differences in de novo detrusor overactivity within 18 months (RR 1.29, 95% CI 0.72–2.30) or at longer-term follow-up between 18 months and 5 years (RR 1.00, 95% CI 0.07–15.12) and after 5 years (RR 1.22, 95% CI 0.40–3.75). Similarly, there were no statistically significant differences in voiding dysfunction (RR 0.82, 95% CI 0.50–1.35).

Overall, there were significantly fewer perioperative complications in the laparoscopic colposuspension group (RR 0.74, 95% CI 0.58–0.96) (Dean et al., 2017). However, intraoperative complications were higher in the laparoscopic group with 21 bladder injuries reported among 521 laparoscopic colposuspensions compared with 10 among 507 open colposuspensions (RR 1.88, 95% CI 0.93–3.83). In addition, injury to the obturator vein was also reported during laparoscopic colposuspension in 2 studies (Carey et al., 2000; Summitt et al., 2000). Women who underwent laparoscopic colposuspension had significantly less pain and needed less postoperative analgesia compared with those undergoing open colposuspension (Dean et al., 2017). All studies, with the exception of Morris et al. (2001), reported the length of hospital stay to be longer for open colposuspension. Similarly, where reported, the time to return to normal activities was longer for open colposuspension. Laparoscopic surgery had significantly longer operative times than open colposuspension in the majority of studies (mean difference 14.06 minutes, 95% CI 11.39–16.73), whereas estimated blood loss was higher in the open groups in all studies that reported these data (Dean et al., 2017).

There were five studies included in the recent Cochrane review (Dean et al., 2017) that looked at different methods of laparoscopic colposuspension. One compared one double-bite suture with two single-bite sutures each side of the urethra (Persson et al., 2000), three compared mesh and staples with sutures (Ankardal et al., 2005; Ross, 1996; Zullo et al., 2002), and the final study compared two different methods of laparoscopic approach (Wallwiener et al., 1995). When comparing subjective cure rates between the one- versus two-suture groups, there was a significantly higher number of women who felt cured (89%) in the two-suture group compared with the one-suture group (65%) (RR 1.37, 95% CI 1.14–1.64). Similar results were found in objective cure with the number of cured women significantly higher in the two-suture group (83%) compared with one-suture (58%) (RR 1.42, 95% CI 1.14–1.77). In comparison of sutures versus mesh and staples in laparoscopic colposuspension, there were better subjective cure rates with sutures within 18 months (RR 1.28, 95% CI 1.11–1.47). Objective cure rates also showed a significantly better outcome in the suture group within 18 months (RR 1.20, 95% CI 1.07–1.35) and continued to favor the suture group at 3 years' follow-up, but this was not statistically significant (RR 1.50, 95% CI 0.83–2.70). Dean et al. (2017) concluded that the number of sutures used appears to have a significant influence on the cure rate, with more sutures resulting in a significantly higher success rate.

Overall, Dean et al. (2017) concluded in their recent Cochrane review that laparoscopic colposuspension appears to have short-term benefits over open surgery, such as less pain, quicker recovery, and fewer perioperative complications, but it appears to take longer to perform compared with open colposuspension. A single trial raises concerns about the long-term performance, but this may reflect a surgical learning effect and is not an independently reliable result. **Recent data on medium-term results from a large, multicenter trial show the effectiveness of laparoscopic colposuspension and are encouraging. If laparoscopic surgery is performed, the use of two paravaginal sutures appears to be the most effective method.**

Barr et al. (2009) looked at the long-term outcome of laparoscopic colposuspension in a report from a 10-year cohort study. A consecutive series of 139 patients who had undergone laparoscopic colposuspension was reviewed and compared with 52 women who had undergone an open colposuspension in the same unit. Subjects were contacted by telephone at least 10 years postoperatively. In total, 96 patients in the laparoscopic group and 31 in the open colposuspension group were available for follow-up. The authors reached the conclusion that laparoscopic colposuspension appeared to be as effective as open colposuspension at long-term follow-up when used as treatment for stress incontinence and could be considered as an alternative surgical approach. Although there is an increase in long-term follow-up results available compared with prior Cochrane reviews, **the place of laparoscopic colposuspension in clinical practice should become clearer when there are longer-term data available.**

In their recent committee paper, Rovner et al. (2017) discussed laparoscopic colposuspension in comparison with minimally invasive mid-urethral slings. Using the evidence from 8 trials, the authors found no statistically significant difference in subjective cure rates within 18 months (RR 0.91; 95% CI 0.80–1.02). Although the definition of objective cure had a large degree of variation between studies, overall the objective cure rate was higher for minimally invasive mid-urethral slings than laparoscopic colposuspension (RR 0.92; 95% CI 0.85–0.99). Compared with laparoscopic colposuspension, the mid-urethral sling procedures had significantly shorter operating time, hospital stay, and time for resuming normal activity.

Key Points: Recommendations From the International Consultation on Incontinence Committee

- Laparoscopic colposuspension can only be recommended for the surgical treatment of SUI in women by surgeons with appropriate training and expertise (grade C recommendation).
- Women should be advised about the limited evidence available about the long-term durability of laparoscopic colposuspension (grade C recommendation).

Data from Rovner E, Anathasiou S, Choo YM, et al.: Surgery for urinary

incontinence in women. In Abrams P, Cardozo L, Wagg A, et al., editors: *Incontinence*, ed 6, Tokyo, Japan, 2017, pp 1741–1854.

Complications of Retropubic Repairs

As with any major abdominal or pelvic surgical procedure, intraoperative and perioperative complications that may occur after a retropubic suspension include bleeding, injury to genitourinary organs (bladder, urethra, ureter), pulmonary atelectasis and infection, wound infection or dehiscence, abscess formation, and venous thrombosis or embolism. Other common complications more specific to retropubic suspension procedures include postoperative voiding difficulty, detrusor overactivity, and vaginal prolapse. Potentially, it is overcorrection of the urethrovesical angle that may be a major contributory factor in the development of the long-term complications of de novo urgency, voiding dysfunction, and enterocele formation.

Nevertheless, the reported incidence of these problems is relatively low. In their meta-analysis, Leach et al. (1997) noted a 3% to 8% transfusion rate for retropubic suspensions and no significant difference in the overall medical and surgical complication rates among retropubic suspensions, needle suspensions, anterior colporrhaphy, and pubovaginal slings. Mainprize and Drutz (1988), in their review of the MMK procedure literature (2712 patients), noted an overall complication rate of 21%, with wound complications and urinary infections making up the majority (5.5% and 3.9%, respectively). Direct surgical injury to the urinary tract occurred in only 1.6%, and genitourinary tract fistulas occurred in 0.3%. Ureteral obstruction has been reported rarely after Burch colposuspension, and it usually results from ureteral kinking after elevation of the vagina and bladder base, although direct suture ligation of the ureter can occur (Applegate et al., 1987). If it is identified intraoperatively, it is best remedied by removal of the offending ligature and temporary placement of a ureteral stent. The so-called post-colposuspension syndrome, which has been described as pain in one or both groins at the site of suspension, has been noted in up to 12% of patients after a Burch procedure (Galloway et al., 1987). More recently, Demirci et al. (2001) reported the occurrence of groin or suprapubic pain in 15 of 220 women (6.8%) after Burch colposuspension with a follow-up of 4½ years.

Postoperative Voiding Difficulty

Postoperative voiding difficulty after any type of retropubic suspension is not uncommon, and undoubtedly its occurrence is more likely if there is preexisting detrusor dysfunction or denervation resulting from extensive perivesical dissection. In most cases, however, it is the result of overcorrection of the urethral axis from inappropriately placed or excessively tightened sutures. If the sutures are placed too medially, they may also transfix the urethra or distort it.

Preoperatively, at-risk patients may be identified by their history of prior voiding dysfunction or episodes of urinary retention. These women should be carefully counseled preoperatively about the potential for postoperative voiding difficulty and the possible need for self-catheterization intermittently. Their incontinence should be of sufficient magnitude that its correction offsets the risk of the need for self-catheterization.

Women with postcystourethropexy voiding problems who have obstruction often do not exhibit the classic urodynamic features of obstruction. However, the history of postoperative voiding symptoms and associated new-onset bladder storage symptoms and a finding of a retropubically angulated and fixed urethra typically indicate that obstruction does exist (Carr and Webster, 1997). In such cases, revision of the retropubic suspension by releasing the urethra into a more anatomic position resolves voiding symptoms in up to 90% of patients (Carr and Webster, 1997; Nitti and Raz, 1994; Webster and Kreder, 1990).

The meta-analysis by Leach et al. (1997) **noted that the risk of temporary urinary retention lasting more than 4 weeks postoperatively is 5% for all retropubic suspensions, and the risk for permanent retention is estimated to be less than 5%. These risks are not significantly different from those for needle suspensions or pubovaginal slings.** Mainprize and Drutz's review of the literature (1988) yielded a 3.6% incidence of postoperative voiding problems after an MMK procedure, whereas the Burch procedure literature reports an incidence of postoperative voiding disorders ranging from 3% to 32% (Alcalay et al., 1995; Colombo et al., 1996a; Eriksen et al., 1990; Galloway et al., 1987; Hilton and Stanton, 1983). In more recent literature, voiding dysfunction may be persistent, as noted in 3.5% of a series of 310 women with a mean follow-up of 36 months (Viereck et al., 2004). Nonpersistent voiding dysfunction has been reported in 12.5% (6% to 37.2%) after primary surgery (Smith et al., 2005). After colposuspension conducted as a secondary procedure, Bidmead et al. (2001) reported voiding difficulties requiring intermittent self-catheterization in 6% of cases.

Because the paravaginal repair aims to restore normal anatomy, there is theoretically little chance of overcorrection of the urethral axis, which should translate into a lower risk of postoperative obstruction. In a study by Richardson et al. (1981), 80% of patients were able to void immediately after paravaginal repair, and “all patients had satisfactory bladder function at the time of discharge.” However, temporary voiding difficulty has been noted in up to 17% of patients after a VOS procedure (German et al., 1994), and chronic (>2 years) voiding difficulty has been noted in up to 11% of patients after the paravaginal repair (Colombo et al., 1996a).

All patients should be counseled before surgery about the potential need for intermittent self-catheterization.

Bladder Overactivity

Bladder overactivity commonly accompanies anatomic SUI, and its incidence preoperatively has been reported to be as high as 30% in patients undergoing either first correction or repeated operations (McGuire, 1981)**. Provided it is considered as a diagnosis, urodynamic evaluation has been performed to show whether detrusor overactivity is present, an attempt at treatment of the related overactive bladder symptoms has been made (with or without success), and the patient has been advised that the presence of detrusor overactivity will increase the risk of continuing storage symptoms postoperatively, then preoperative bladder overactivity does not contraindicate a retropubic suspension procedure, provided that anatomic SUI has also been demonstrated.** In the majority of patients, the bladder overactivity symptoms resolve after surgical repair (McGuire, 1988). A meta-analysis by Leach et al. (1997) found the risk of urgency after a retropubic suspension to be 66% if urgency and detrusor overactivity were present preoperatively, 36% if there was urgency but no documented overactivity preoperatively, and only 11% if there was neither urgency nor overactivity preoperatively. There was no significant difference in the incidence of postoperative urgency among retropubic suspensions, needle suspensions, and pubovaginal slings. Postoperative urgency was noted in only 0.9% of MMK procedures in Mainprize and Drutz's meta-analysis of 15 series (1988), although Parnell et al. (1982) reported that 28.5% of their patients developed postoperative storage symptoms. Jarvis's meta-analysis (1994b) of Burch procedures found the incidence of de novo bladder overactivity to be 3.4% to 18%. More recently, Smith et al. (2005) quoted a figure for postoperative detrusor overactivity of 6.6% for colposuspension (range 1.0% to 16.6%), whereas the incidence of postoperative urgency or urgency incontinence after the paravaginal or VOS repair has been reported to be 0 to 6% (Colombo et al., 1996a; German et al., 1994; Shull and Baden, 1989).

For patients in whom postoperative storage symptoms persist, proven to be associated with detrusor overactivity and intractable to management with anticholinergic therapy and behavioral modification, surgical techniques including intravesical botulinum toxin therapy, neuromodulation, augmentation cystoplasty, or detrusor myectomy may be indicated.

Bladder storage symptoms arising de novo after retropubic suspension may be associated with bladder outlet obstruction. This premise is supported by the frequent coexistence of these symptoms with impaired voiding after suspension procedures and confirmed by the finding that urethrolysis, by freeing the urethra from an obstructed position, often resolves storage and voiding symptoms (Raz, 1981; Webster and Kreder, 1990).

Vaginal Prolapse

Retropubic suspensions alter vaginal and bladder base anatomy, thus postoperative vaginal prolapse is a potential complication. Genitourinary prolapse has been reported as a sequel to Burch colposuspension in 22.1% of women (range 9.5% to 38.2%) by Smith et al. (2005) in their review of the literature. **The Burch procedure, because of lateral vaginal elevation, may aggravate posterior vaginal wall weakness, predisposing to enterocele.** The incidence varies from 3% to 17% (Burch, 1961, 1968; Galloway et al., 1987; Wiskind et al., 1992); **because of this, prophylactic obliteration of the cul-de-sac of Douglas is sometimes considered in performing retropubic suspensions** (Shull and Baden, 1989; Turner-Warwick and Kirby, 1993). However, simultaneous hysterectomy is not recommended prophylactically because it does not enhance the outcome of a retropubic suspension and should be performed only if there is concomitant uterine disease (Langer et al., 1988; Milani et al., 1985). Although the Burch procedure and paravaginal or VOS repair correct lateral defect cystourethroceles, recurrent cystourethroceles have been noted in 11% and 39% of Burch procedures and paravaginal repairs, respectively (Colombo et al., 1996a). In Mainprize and Drutz's review (1988), postoperative cystocele was noted in only 0.4% of patients after an MMK procedure.

Wiskind et al. (1992) noted that 27% of patients who had undergone a Burch colposuspension developed prolapse requiring surgery: rectocele in 22%, enterocele in 11%, uterine prolapse in 13%, and cystocele in 2%. More recently, it has been suggested that most women are asymptomatic, and less than 5% have been reported to request further surgery (Smith et al., 2005). Ward and Hilton (2004) reported that 4.8% of women needed a posterior repair, whereas Kwon et al. (2003) reported that 4.7% required subsequent pelvic reconstruction.

Auwad et al. (2006) reported the findings of the first prospective study to determine the prevalence of POP after colposuspension and to investigate possible preoperative and operative risk factors. Seventy-seven women who underwent colposuspension from 1996 to 1997 were investigated. POP was assessed before colposuspension using the POP-Q. Women were reassessed at 1 and 7 to 8 years (or when referred with symptomatic POP). By 7 to 8 years, of the 77 women, 29 (38%) had developed symptomatic prolapse, 29 (38%) had asymptomatic prolapse, 7 (9%) had no symptoms and no prolapse, and 12 (16%) could not be assessed. POP at 1 year was significantly associated with the presence of posterior vaginal descent before colposuspension (OR 3.07, 95% CI 1.10 to 8.60, $P = 0.03$). No potentially predisposing variable reached statistical significance by 8 years postcolposuspension. The results add support to the view that there is an association between colposuspension and the development of symptomatic POP (requiring surgery).

Key Point: Complications of Retropubic Repairs

- Because retropubic suspensions are unable to correct central defect cystoceles, patients must be carefully examined preoperatively to exclude their presence and must be counseled if undergoing a colposuspension because of the high risk of needing further surgery in the long term. Particularly, those in whom a weakness of the posterior compartment is identified preoperatively and those with a past history of hysterectomy may be at increased risk.

Comparisons of Incontinence Procedures

Retropubic Repair Versus Needle Suspension and Anterior Repair

Three articles that reviewed the literature on incontinence procedures found retropubic suspensions to be more effective than either needle suspensions or anterior colporrhaphies (Black and Downs, 1996; Jarvis, 1994b; Leach et al., 1997). Cure rates were approximately 85% for the retropubic suspensions compared with 50% to 70% for the needle suspensions and anterior colporrhaphies. Results were more durable for the retropubic suspensions and better if the procedure was primary. A recent Cochrane review by Lapitan et al. (2017) found that fewer women were incontinent after colposuspension, 11%, compared with needle suspension, 15%, in the first year after surgery (RR 0.66%; 95% CI 0.42–1.03). Although incontinence rates increased over time after both procedures, there were a lower percentage of women who were incontinent more than 5 years after surgery in the colposuspension group, 18%, compared with the needle suspension group, 57% (RR 0.32; 95% CI 0.15–0.71). Overall, there is now high-level evidence to indicate that open colposuspension has better outcomes than anterior colporrhaphy, bladder neck needle suspension, and MMK procedure (evidence level 1) (Rovner et al., 2017).

Key Point: Recommendation From the International Consultation on Incontinence Committee

- Endoscopic and nonendoscopic bladder neck needle suspension procedures, with and without bone anchors, are not recommended for the treatment of SUI (grade A recommendation).

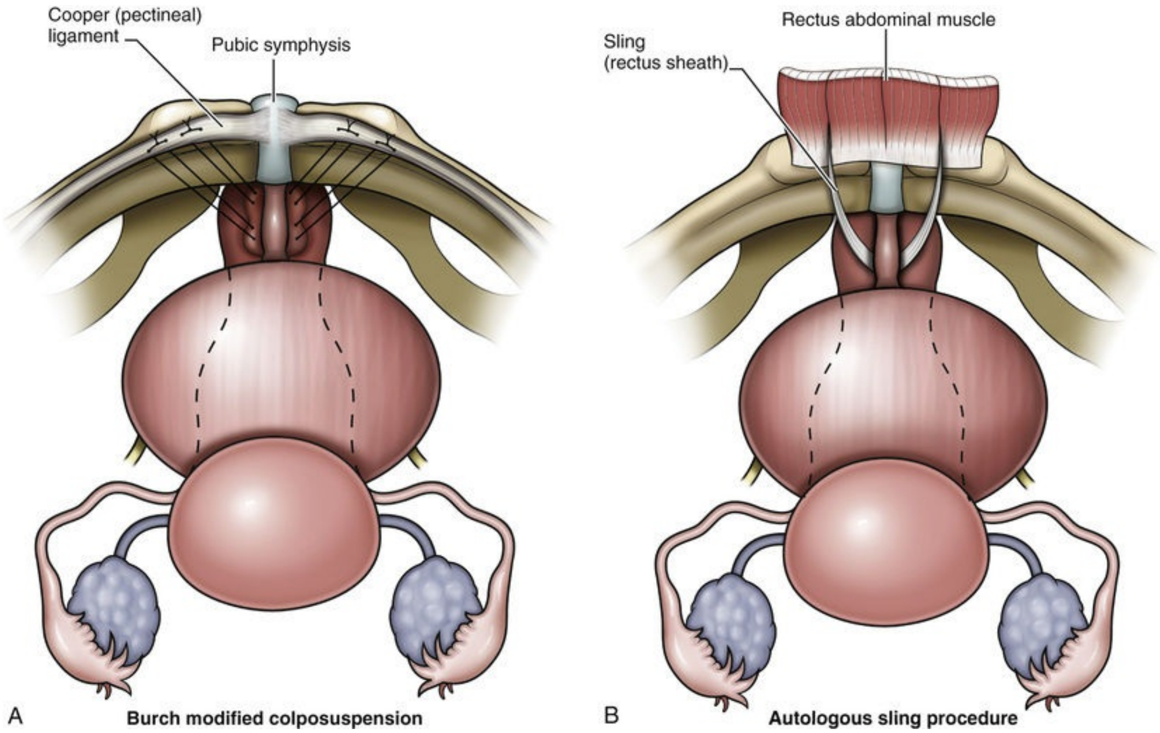
Data from Smith AR, Chang D, Dmochowski R, et al.: Committee 14. Surgery for urinary incontinence in women. In Abrams P, Cardozo L, Khoury S, et al., editors: *Incontinence*, Plymouth, UK, 2009, Health Publications, pp 1191–1272.

Retropubic Repair Versus Pubovaginal Sling

Most studies in the historical literature have not demonstrated a significant difference in cure rates between retropubic suspensions (usually a Burch procedure) and pubovaginal slings (Black and Downs, 1996; Jarvis, 1994b; Leach et al., 1997). However, often, selection bias exists in that the pubovaginal sling is usually reserved for patients with multiple prior failed incontinence procedures, with less prolapse, and the presence of presumed intrinsic sphincter deficiency (a fixed urethra with periurethral fibrosis) is often used in clinical practice as a contraindication to a retropubic suspension. In an interesting randomized study in patients with a prior failed incontinence procedure (anterior repair) but without a low-pressure urethra (i.e., MUCP <20 cm H_2O), Enzelsberger's group (1996) found no significant difference in cure (subjective or objective) at 32 to 48 months between the Burch procedure and the Lyodura sling. However, they noted significantly more postoperative voiding difficulty with the pubovaginal sling (13% vs. 3%) and more vaginal prolapse (enterocele or rectocele) with the Burch procedure (13% vs. 3%).

A high-quality multicenter randomized clinical trial in women with stress incontinence compared the Burch colposuspension with a pubovaginal sling, using autologous rectus fascia (Aldo et al., 2007). Women were eligible for the study if they had predominant symptoms associated with the condition, a positive stress test result, and urethral hypermobility. The primary outcomes were success in terms of overall urinary-incontinence measures, which required a negative pad test result, no urinary incontinence (as recorded in a 3-day diary), a negative cough and Valsalva stress test result, no self-reported symptoms, and no retreatment for the condition, and success in terms of specific measures of stress incontinence as well as an assessment of postoperative urgency incontinence, voiding dysfunction, and adverse events. A noteworthy aspect of the study was the careful approach to standardization (using the recommendations from the standardization committees of the International Continence Society) with regard to clinical terms, urodynamic nomenclature, and methods of evaluation of patients across all sites. Key elements of the two surgical procedures were standardized among all participating surgeons and included the use of preoperative antibiotics, skin-incision length, number and type of Burch sutures, fascial-sling length and width, and cystoscopic evaluation of the bladder. A criticism that can be leveled at the study is the choice of technique for the Burch colposuspension with very medial paraurethral sutures.

The techniques utilized are demonstrated in Fig. 123.7.



Cooper (pectineal) ligament
Pubic symphysis
A
Burch modified colposuspension
Sling (rectus sheath)
Rectus abdominal muscle
B
Autologous sling procedure

FIG. 123.7 In the Burch colposuspension (A), sutures are placed in the anterior vaginal wall at the level of the bladder neck and proximal urethra and sutured to the iliopectineal ligament. In the autologous sling procedure (B), a strip of rectus fascia is harvested and permanent sutures placed at both ends. The sling is positioned beneath the urethra via a vaginal incision. The two ends of the sling are then secured to the anterior abdominal wall, either together or to the rectus fascia. (Modified from Aldo ME, Richter HE, Brubaker L, et al.: Burch colposuspension versus fascial sling to reduce urinary stress incontinence. *N Engl J Med* 356:2143–2155, 2007.)

Because these procedures are frequently performed in conjunction with surgery for pelvic prolapse, abdominal and vaginal approaches for pelvic prolapse repair and hysterectomy were permitted; however, surgeons were required to declare before randomization which concomitant procedures would be performed.

A total of 655 women were randomly assigned to study groups: 326 to undergo the sling procedure and 329 to undergo the Burch procedure; 520 women (79%) completed the outcome assessment. At 24 months, success rates were higher for women who underwent the sling procedure than for those who underwent the Burch procedure, for the overall category of success (47% vs.

38%, $P = 0.01$) and the category specific to stress incontinence (66% vs. 49%, $P < 0.001$). There was no significant difference between the sling and Burch groups in the percentage of patients who had serious adverse events (13% and 10%, respectively; $P = 0.20$). However, more women who underwent the sling procedure had adverse events than in the Burch group, with 415 events among 206 women in the sling group as compared with 305 events among 156 women in the Burch group. This difference was primarily the result of urinary tract infections; 157 women in the sling group (48%) had 305 events and 105 women in the Burch group (32%) had 203 events. When urinary tract infections were excluded, the rates of adverse events were similar between the two groups.

The distribution of time to return to normal voiding differed significantly between the two groups ($P < 0.001$). Voiding dysfunction was more common in the sling group than in the Burch group (14% vs. 2%, $P < 0.001$). Consequently, surgical procedures to reduce voiding symptoms or improve urinary retention were performed exclusively in the sling group, in which 19 patients underwent 20 such procedures. (63% vs. 47%, $P < 0.001$). Treatment-satisfaction rates for the 480 patients who answered the satisfaction question at 24 months were significantly higher in the sling group than in the Burch group (86% vs. 78%, $P = 0.02$).

A further analysis of this study focused on sexual activity as assessed by the Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ)-12 among those sexually active at baseline and 2 years after surgery (Brubaker et al., 2009). This report demonstrated that sexual function improves after successful surgery and does not differ between Burch and sling procedures.

Chai et al. (2009) reviewed complications in women undergoing Burch colposuspension versus autologous rectus fascial sling for SUI. These authors reviewed serious adverse events in the Stress Incontinence Surgical Treatment Efficacy Trial (SISTEr). The conclusion reached was that concomitant surgery and continence procedures increased the risk of complications. Sling surgery was associated with a higher risk of cystitis within the first 6 weeks postoperatively, and intermittent self-catheterization increased the risk of cystitis in this group. Complications were associated with surgical factors and not with patient-related factors. The authors concluded that blood loss and operative time were significantly associated with adverse events. Intermittent self-catheterization increased the cystitis rate by 17% and 23% in the Burch and sling groups, respectively.

Kraus et al. (2011) reported on changes in urodynamic measures 2 years after

Burch colposuspension or autologous sling surgery in a report from this large study (SISTEr). They noted that 655 women underwent standard urodynamic studies before and 2 years after Burch or sling surgery. The conclusion reached was that the Burch colposuspension and autologous fascial sling procedure were associated with similar decreases in noninstrumental flow rates and that slings were associated with great increase in the detrusor pressure at maximum flow and bladder outlet obstruction index. They concluded that these changes suggested that both procedures were effective in part because of increasing outlet resistance; it was suggested that sling procedures may be more obstructive based on the urodynamic parameters measured.

Richter et al. (2012) reviewed patient-related factors associated with long-term urinary continence after Burch colposuspension and pubovaginal fascial sling surgery in a long-term follow-up of SISTEr. The follow-up of patients in this study was up to 7 years after surgery. The authors concluded that urinary continence rates decreased during a period of 2 to 7 years postoperatively from 43% to 13% in the Burch group and from 53% to 27% in the sling group. The baseline factors included in the first multivariate model were age, prior SUI surgery, menopausal state, urge index, assigned surgery, and recruiting site. All of these were independently associated with increased risk of incontinence. In the final multivariate model, included baseline and postoperative factors were Burch surgery, baseline variables of prior urinary incontinence surgery, menopausal state, and postoperative urge index. All of these were significantly associated with a greater risk of recurrent urinary incontinence. The authors concluded that preoperative and postoperative urgency incontinence symptoms, Burch urethropexy, prior SUI surgery, and menopausal status were negatively associated with long-term continence rates. More effective treatment of urgency urinary incontinence in patients who undergo SUI surgery may improve long-term overall continence rates. They concluded that in women followed for a minimum of 5 years after Burch colposuspension or pubovaginal fascial sling, prior SUI surgery, being menopausal without hormone replacement therapy, having undergone a Burch procedure, and increased postoperative urgency incontinence symptoms were significantly associated with long-term incontinence. The final conclusion was that knowledge of risk factors for surgical failure can be used to better inform patients of the likelihood of long-term continence or decreased continence rates to be experienced as a result of the surgery. The suggestion put forward is that overall continence status may be improved by proactive preoperative and postoperative assessment and effective treatment of urgency incontinence.

According to a recent Cochrane review by Lapitan et al. (2017), **autologous fascia pubovaginal sling is modestly more effective than colposuspension at mid-term to long-term follow-up, albeit with a higher rate of early postoperative voiding dysfunction.** Based on the limited data available, it is suggested that the overall rates of late surgical complications are similar after pubovaginal sling and colposuspension. Rovner et al. (2017) concluded that there is an insufficient database on which to recommend or differentiate these procedures on the basis of adverse events or complications alone. It can be reliably concluded that in specialist centers working in a standardized fashion**, the autologous fascial sling results in a higher rate of successful treatment of stress incontinence but also greater morbidity than the Burch colposuspension.**

Key Point: Recommendations From the International Consultation on Incontinence Committee

- Autologous fascia pubovaginal sling is recommended as an effective treatment for female SUI, which has longevity for primary and revision surgery (grade A recommendation).

Data from Rovner E, Anathasiou S, Choo YM, et al.: Surgery for urinary incontinence in women. In Abrams P, Cardozo L, Wagg A, et al., editors: *Incontinence*, ed 6, Tokyo, Japan, 2017, pp 1741–1854.

Burch Colposuspension Versus Marshall-Marchetti-Krantz Procedure Versus Paravaginal Repair

In general, comparisons between the MMK and the Burch procedures have yielded similar results. Jarvis, in his meta-analysis of the literature (1994b), noted that overall continence rates were 89.6% and 83.9% for the MMK and the Burch procedures, respectively. When he looked at the effect of prior incontinence surgery, the continence rates were 92.1% and 94% when there was no prior surgery and 84.5% and 84% when there was a history of prior incontinence surgery for the MMK and Burch procedures, respectively. Similarly, Black and Downs (1996), in reviewing five studies (one randomized) that directly compared the MMK procedure with the Burch procedure, found that there was no significant difference in cure rates between the two procedures, although the Burch procedure yielded better results in general. However, they pointed out that overall the studies were of poor quality with small sample sizes.

Two randomized studies that assessed urethral sphincteric function by urethral pressure profilometry had conflicting results. Quadri's group (1999) compared the MMK procedure with the Burch procedure in women with a hypermobile, low-pressure urethra (MUCP <20 cm H_2O) and noted significantly higher subjective and objective 1-year cure rates with the MMK procedure. They used urethroscopy to facilitate MMK suture placement. On the other hand, Colombo's group (1994) excluded women with a low-pressure urethra (MUCP <30 cm H_2O) and performed a cystotomy to facilitate MMK suture placement. With 2- to 7-year follow-up (mean, 3 years), they noted higher subjective and objective cure rates with the Burch procedure, although these were not statistically significant. In addition, significantly more MMK patients had persistent postoperative voiding difficulties (28% vs. 8%).

The literature on the paravaginal repair is sparse. The only randomized study that compared the Burch procedure with a paravaginal repair found significantly greater subjective and objective cure with the Burch procedure (Colombo et al., 1996a). Until large, randomized studies with prolonged follow-up are available, the issue of which is the best procedure will remain unresolved.

Tension-Free Vaginal Tape Procedure Versus Colposuspension

Since its introduction in 1996 by Ulmsten, the TVT procedure has gained widespread acceptance for treatment of SUI, given its low morbidity, its short-term success rates, and the fact it can be performed as an outpatient procedure with use of a local or regional anesthetic (Ulmsten et al., 1996). The 7-year objective and subjective success rate for TVT is 81% (Nilsson et al., 2004). In a more recent review of this series by Nilsson et al. (2013) at 17 years' follow-up, 74 of the initial cohort of 90 women (82%) were potentially available for follow-up and of these, 78% could be contacted and capable of cooperating by clinic visit (46 women) or telephone interview (12 women). The objective cure rate, assessed by negative stress test, was found to be 91% and did not show a decline between 5 and 17 years' follow-up. The authors found a corresponding subjective perception of either cure or improvement of 87%, with a slight decline during the last 6 years. There was one woman who was found to have a small, asymptomatic mesh erosion, which had not been previously present on vaginal exam at 7 years' follow-up (Nilsson et al., 2013).

There have been a number of well-designed, prospective, randomized trials comparing the Burch colposuspension with TVT. Liapis et al. (2002) reported a prospective randomized comparative study of Burch colposuspension ($n = 35$) and TVT ($n = 36$). They concluded that at 2-year follow-up, the TVT and Burch procedures were equally effective with an objective pad test cure rate of 84% and 86%, respectively. TVT had a shorter operative time and entailed less postoperative pain with a faster return to normal activity.

Ward and Hilton (2004) published a 2-year follow-up of their landmark prospective randomized trial comparing TVT and open Burch colposuspension. At 2 years, 74% of the initial TVT and 69% of the open colposuspension patients completed the evaluation. The objective cure rates for the TVT (81%) and colposuspension (80%) were not significantly different. However, if the missing patients were evaluated by the last observation carried forward analysis, the cure rates would favor TVT (78% vs. 68%). The subjective cure rates differ from the objective rates dramatically, with only 43% and 37% reporting subjective cure of stress incontinence after TVT and colposuspension, respectively. At 2 years, the colposuspension group still had significantly lower scores on mental and emotional health. The incidences of enterocele and vault prolapse were higher in the colposuspension group, requiring significantly more prolapse surgery. Likewise, the number of patients still requiring intermittent catheterization was higher in the colposuspension group. The intraoperative complications were higher in the TVT group, whereas the postoperative complications were higher in the colposuspension group. The authors' conclusion at 2 years, because of patients lost to follow-up, was unchanged from their conclusion at 6 months, namely, that TVT may be better than, worse than, or the same as colposuspension.

In a further report from the Ward and Hilton study, 98 of those who had TVT and 79 of those who had colposuspension returned for 5-year follow-up; 72 in the TVT group and 49 in the colposuspension group had full subjective and objective data (Ward et al., 2008). The primary outcome in this analysis was a negative 1-hour pad test result, and this was not significantly different between the two groups: 58 of 72 (81%) women in the TVT group and 44 of 49 (90%) in the colposuspension group (*P* = 0.021, Fisher's exact test) at 5 years. Significantly, more women in the colposuspension group (11 [7.5%]) underwent surgery for prolapse during the follow-up period than those in the TVT group (3 [1.8%]). Tape-related complications were seen in 6 women. In the first year, 1 tape was divided for obstructed voiding; there was 1 suprapubic extrusion and 1 vaginal erosion. Two further vaginal erosions were detected at 5-year follow-up, and in addition, 1 woman was found to have tape within the bladder at cystoscopy after complaining of overactive bladder symptoms. There were no reported suture-related complications in the colposuspension group. The effect of both procedures on cure of incontinence and improvement in quality of life appears from this follow-up of a portion of the originally treated patients to be maintained in the long term out to 5 years (Ward et al., 2008). Eight-one percent of the women who had undergone TVT and 90% who had undergone colposuspension regarded themselves as satisfied or very satisfied with the results of their surgery at 5 years.

A Cochrane review of open colposuspension examined a total of 12 trials comparing open retropubic colposuspension and TVT (Lapitan et al., 2017). In the short term within 1 year of treatment, medium term 1 to 5 years', and long term more than 5 years' follow-up, there was no statistically significant difference between the two treatment groups in the risk for incontinence as assessed subjectively. In the objective assessment of incontinence, the results were similar with no statistically significant differences within any time periods between the retropubic colposuspension and TVT groups.

Key Points: Long-Term Efficacy of Tension-Free Vaginal Tape and Colposuspension

- The Cochrane review concluded that TVT trials have shown noninferiority in terms of cure rates when compared with open colposuspension.
- Clinicians should inform women of the differences in adverse events between the two procedures. Open colposuspension has been shown to be associated with POP, particularly in the long term, whereas sling operatives put women at a higher risk for postoperative voiding dysfunction. Late tape erosion may occur several years after surgery.

Data from Lapitan MCM, Cody JD, Mashayekhi A: Open retropubic colposuspension for urinary incontinence in women. *Cochrane Database Syst Rev* 7:CD002912, 2017.

Persson et al. (2002) were one of the first groups to compare TVT and laparoscopic Burch colposuspension. At 1-year follow-up, there was no difference between objective and subjective cure rates. Valpas et al. (2004) conducted a prospective randomized trial comparing TVT and laparoscopic mesh colposuspension at 1-year follow-up. The objective cure rate (negative stress test result, 86% vs. 57%), satisfaction, and quality of life were statistically better for the TVT group.

Paraiso et al. (2004) prospectively randomized 72 patients into laparoscopic Burch colposuspension and TVT at a mean follow-up of 20 months, but only 17 and 16 patients were available in the laparoscopic and TVT groups, respectively. Whereas objective and subjective cure rates were significantly higher in the TVT group, satisfaction of patients was equal in each group, and no difference was reported in voiding dysfunction, urgency, or symptomatic pelvic prolapse. All these laparoscopic studies require longer follow-up with greater power to demonstrate a persistent difference between TVT and Burch colposuspension.

A recent Cochrane review by Dean et al. (2017) reviewed eight trials comparing laparoscopic colposuspension with “self-fixing” slings, or tension-free vaginal tape. Overall, the authors found that subjective cure rates are equally good for both of these minimally invasive techniques, in the short and long term. The objective cure rate within 18 months appeared to favor the vaginal sling technique when compared with laparoscopy using mesh or sutures. There were no significant differences between the two procedures in terms of postoperative voiding dysfunction, de novo detrusor overactivity, and perioperative complications; however, laparoscopic colposuspension had a longer operative time, longer hospital stay, and slower return to normal activities. Based on these results, the authors concluded that **“self-fixing” slings are as, if not more, clinically effective than laparoscopic colposuspension;** however, more longer-term data are needed to better assess long-term outcomes (Dean et al., 2017). As the skill needed to perform laparoscopic colposuspension is greater than that needed for TVT sling placement, many surgeons training in the stress urinary incontinence surgeries are more likely to become efficient in the sling procedures.

The shift in practice pattern away from Burch colposuspension for the treatment of SUI to mid-urethral slings as the primary treatment of SUI shows one of the difficulties in conducting surgical RCTs, especially when the field has changed as quickly as it has in recent years in the treatment of urinary incontinence. A recent survey of urogynecology fellows found that the average third-year fellow had performed 257 mid-urethral sling procedures and only 13 Burch procedures (LeBrun et al., 2008). It would be interesting to determine if surgeon's experience with Burch colposuspension is correlated with outcomes. Indeed, the outcomes reported in the existing literature base are likely to be very different from those seen in many clinicians' clinical practices, where this has become a rare operation and where many have had very limited experience of carrying out the procedure during their training over the last decade.

A 10-year follow-up study reached the conclusion that TVT is more cost effective than Burch colposuspension in the treatment of female SUI (Laudano et al., 2013). The conclusion reached was that the cost and the effectiveness of TVT affected the cost-effectiveness analysis. The major criticism of any such study is that it does not take account of potential complications, which are never adequately considered in any such study, bearing in mind the potential publication bias in the literature toward best practice from specialized centers and the concern that the complications seen in real-life practice may not be reflected in the published literature. Nevertheless, this is a well-conducted study and does provide clear evidence that TVT is a cost-effective alternative.

At this time, TVT appears to be an equivalent operation to the open or laparoscopic Burch colposuspension. TVT or transobturator tape (TOT) procedures have now largely supplanted colposuspension in contemporary practice. An open colposuspension should still be considered as a surgical option in patients undergoing open surgery and still has a role when there is associated prolapse. Laparoscopic colposuspension has been shown in the short term to have some advantages over open colposuspension in experienced hands, but as a procedure has largely been supplanted by TVT or TOT in contemporary practice.

World Without Mesh

The use of synthetic mesh in female pelvic medicine and reconstructive surgery has been the subject of a large degree of controversy and litigation in recent years. In July 2011 the US Food and Drug Administration (FDA) re-classified transvaginal mesh used specifically for POP as "high risk" while maintaining tapes used for SUI as "low risk." They state on their website that the safety and efficacy of multi-incision slings (tapes) have been well established in clinical trials that followed patients for up to 1 year. A position statement released by the Society of Urodynamics, Female Pelvic Medicine and Urogenital Reconstruction (SUFU) and the American Urogynecologic Society (AUGS), supported by other professional bodies and the American Urological Association (AUA), strongly supported the FDA decision in regard to tapes for SUI.

After the FDA warning about the use of transvaginal mesh for POP repair in 2011, many products were withdrawn from the market under pressure generated by numerous lawsuits after severe complications with this technique (Sedrakyan et al., 2016). Despite the consistent differentiation between tapes/slings for stress incontinence and transvaginal mesh for prolapse by the FDA and other international scientific associations (FDA, 2018; Haylen et al., 2011), litigation and plaintiff lawyers as well as the general public, do not make a distinction between these two scientifically different products, placed in a different anatomic location to treat different pelvic floor problems. As a consequence of these misconceptions and increased media attention, mid-urethral slings have also come under scrutiny, leading to some government jurisdictions taking steps toward severe restrictions or even banning synthetic slings (Haylen et al., 2018). In fact, these products are the subject of ongoing lawsuits filed by the states of Washington, California, Kentucky, and Mississippi, which claim that Johnson & Johnson did not fully disclose the potential risks and side effects of surgical mesh.

As the use of synthetic tapes for midurethral slings come under increased restriction, it may boost the resurgence of open or laparoscopic Burch colposuspension as a first-line surgical treatment for stress urinary incontinence (Veit-Rubin et al., 2019). However, the experience of many clinicians with any of these alternate options may be little or none, leaving an enormous number of incontinence sufferers and their surgeons without a first-line minimally invasive surgical option (Haylen et al., 2018). It is therefore imperative that training in open and laparoscopic Burch colposuspension be provided in residency and fellowship training programs worldwide to afford the next generation of surgeons the ability to offer these procedures to their patients. **It is essential to counsel patients on the different types and qualities of synthetic mesh implants, their uses, and alternatives. As synthetic mesh use becomes more restricted, there may be a change in practice toward autologous sling material and colposuspension in the future.**

Key Points: Retropubic Suspension Surgery for Incontinence

- Anti-incontinence surgery does not necessarily work by restoring the same mechanism of continence that was present before the onset of incontinence. It works by a compensatory approach.
- The surgeon's preference, coexisting problems, and anatomic features of the patient and her general health condition influence the choice of procedure.
- There is lack of a clear consensus regarding which surgical procedure for stress incontinence is most effective, but contemporary practice is shifting to the urethral sling being the most widely used and having largely replaced the colposuspension.
- A number of variables may influence surgical outcome: age, postoperative activity, medical comorbidity, obesity, duration of symptoms, coexistence of detrusor overactivity, prior surgery, and intrinsic sphincter deficiency.
- There is no consensus on how to differentiate the relative contributions of hypermobility and sphincteric weakness.
- There remains no consensus on how to assess the outcomes of surgery, but this requires careful assessment with adequate follow-up and use of simple objective measures as well as taking particular account of patient-perceived outcomes.
- During short-term follow-up, vaginal and open retropubic suspension procedures have similar success rates. With longer follow-up (and with the exception of the pubovaginal sling), patients who have retropubic procedures fare better.
- With the MMK procedure, placement of sutures through the pubic symphysis incurs the risk of osteitis pubis in 0.9% to 3.2% of patients.

- Burch colposuspension is as effective as any other procedure in primary or secondary surgery at curing SUI, with proven long-term success. Thus it should be regarded as the *standard* open retropubic procedure for incontinence.
- Abdominal paravaginal repair is less effective than other forms of colposuspension.
- As with any major abdominal or pelvic surgical procedure, intraoperative and perioperative complications that may occur after a retropubic suspension include bleeding, injury to genitourinary organs (bladder, urethra, ureter), pulmonary atelectasis and infection, wound infection or dehiscence, abscess formation, and venous thrombosis or embolism. Other common complications more specific to retropubic suspension procedures include postoperative voiding difficulty, detrusor overactivity, and vaginal prolapse.
- The risk of temporary urinary retention lasting more than 4 weeks postoperatively is 5% for all retropubic suspensions. The risk of permanent retention is estimated to be less than 5%. These risks are not significantly different from those of needle suspensions or pubovaginal slings.
- All patients should be counseled before surgery about the potential need for intermittent self-catheterization.
- Because retropubic suspensions are unable to correct central defect cystoceles, patients must be carefully examined preoperatively to exclude their presence. The Burch procedure, because of lateral vaginal elevation, may aggravate posterior vaginal wall weakness, predisposing to enterocele.
- Retropubic suspensions are more effective than either needle suspensions or anterior colporrhaphies.
- Laparoscopic colposuspension is not recommended as a routine surgical procedure and, when performed, should be carried out only by a surgeon skilled in laparoscopic surgery.
- Most studies in the literature have not demonstrated a significant difference in cure rates between retropubic suspensions (usually a Burch procedure) and pubovaginal slings.
- Comparisons between the MMK procedure and the Burch procedure have yielded similar results in general.
- The literature on the paravaginal repair is sparse. The only randomized

study that compared the Burch procedure with a paravaginal repair found significantly greater subjective and objective cure rates with the Burch procedure.

- At this time, the TVT procedure appears to be at least equivalent to the Burch colposuspension, and in general is probably better.
- As synthetic mesh use becomes more restricted and controversial, there may be a change in practice toward autologous sling material and colposuspension in the future.

Vaginal and Abdominal Reconstructive Surgery for Pelvic Organ Prolapse

---

Jack Christian Winters MD, FACS, Ryan M. Krlin MD, Barry Hallner MD

Preparing the Patient for Prolapse Surgery

Because pelvic organ prolapse (POP) is, for the most part, a quality-of-life (QoL) issue, consideration must be given to the stage of prolapse, patient's symptoms, and the degree to which the patient's QoL is impaired (Novara and Artibani, 2005). In selecting surgical procedure(s), urologists must individualize management based on the unique clinical presentation of each patient, taking into account physiologic age, comorbidities, previous surgeries, and level of physical and sexual activity, as well as overall bother from POP symptoms (Flynn and Webster, 2002). Once the decision has been made to proceed with surgery, it is imperative to recall that the best chance at restoring normal support and function is most likely associated with the first surgery (Rogers, 2003). After the first procedure, the normal anatomic planes will no longer be present, which may add to the difficulty and complexity of subsequent surgeries. It has been demonstrated that recurrence rates increase with each attempt to surgically correct the defect(s) (Birch, 2005; Maher and Baessler, 2006a,b). A preoperative discussion is warranted to inform patients of the anticipated risks and benefits of each surgical option so that they can choose the type of operation (if any) is best for them. Some may feel that their level of bother may not warrant the risks of prolapse surgery, and that is a reasonable informed decision.

Prolapse repairs can be defined as restorative, compensatory, and obliterative (Van Rooyen, 2005). In patients whose comorbidities preclude prolonged surgery, obliterative procedures may offer symptom relief with minimal morbidity. These procedures are contraindicated in patients who wish to remain sexually active; however, for the right candidate these procedures can greatly reduce symptoms with lower risk. For those patients who have discrete defects in the fibromuscular layer of the endopelvic fascia, restorative repairs are an appropriate option. These repairs correct the defined defects in the native tissues by using endogenous support structures. For patients whose native tissues are particularly weak or in those who have had failed surgeries, compensatory procedures, which may include insertion of a graft, may be used. Grafts are made of synthetic materials, biologic, and autologous tissues.

Pelvic floor reconstruction may be performed through a vaginal, open abdominal, laparoscopic, or robotic approach or any combination of these techniques. Because POP is often mixed, surgery commonly involves a combination of repairs addressing all affected compartments. In addition, an anti-incontinence procedure may be performed at the same time. In regard to vaginal and abdominal approaches to prolapse surgery, both approaches offer high degrees of patient satisfaction and low rates of recurrent surgery for prolapse. Abdominal techniques are readily performed by laparoscopic/robotic approaches, with some evidence suggesting these repairs are more durable compared with vaginal techniques (Benson et al., 1996). It is important that all of these factors be considered when selecting the proper technique for each patient.

Preoperative Counseling of Patient for Vaginal Pelvic Organ Prolapse Surgery

It is clear that success after prolapse surgery is not just objective resolution of the anatomic defects. The absence of patient symptoms, whether resolution of vaginal bulging and/or minimizing de novo postoperative symptoms, has the strongest correlation with the patient's assessment of overall improvement and treatment success (Barber et al., 2009). Thus t**he concept (and definition) of success must include patient satisfaction and symptom improvement in addition to objective measures.** This process begins before the operation, as patients' expectations and readiness to undergo surgery for POP has been shown to affect their satisfaction and how they perceive their improvement (Kenton et al., 2007). Elkadry et al. (2003) found that patient satisfaction after surgery for POP correlated highly with achievement of self-described goals. Thus it is very useful to inquire of patients, "What are you expecting after surgery? What changes do you desire?" Furthermore, patients perceived the experience of routine postoperative events such as pain, hospital discharge with a catheter, constipation, urgency incontinence, and minor effects of anesthesia as surgical complications. These perceived complications were also associated with dissatisfaction, which existed despite high cure rates. A feeling of being unprepared for surgery was highly associated with a negative perception of outcome. **Thus negative patient perception equates with postoperative dissatisfaction even in the presence of high objective cure rates. It is vital to recognize that the absence of symptoms influences patient satisfaction greater than the elimination of anatomic prolapse.**

Kenton et al. (2007) evaluated patients with standardized counseling, which involved a 3-page handout on what to expect after surgery. Women who perceived they were fully prepared for surgery were more likely to be improved on the Patient Global Impression of Improvement (PGI-I) (Yalcin and Bump, 2003) and had lower postoperative Pelvic Organ Prolapse Distress Inventory (POPDI) (Barber et al., 2001) and Urinary Distress Inventory (UDI) (Shumaker et al., 1994) scores. Also, they found that objective measures of cure did not differ by preparedness. In conclusion, **the preoperative surgeon-patient interaction is vital and may facilitate improved postoperative patient satisfaction. Therefore it is recommended to complete a thorough consent about the surgery, alternatives to surgery, the purpose of planned surgery (what it can and cannot accomplish), the benefits of surgery (what symptoms can be improved), the risks, and complications. In addition, it is useful to review what to expect while the patient is in the hospital, what to expect at home, and strategies on coping with a catheter in the hospital and at home if needed** (Kenton et al., 2007).

Key Points: Preoperative Counseling for Pelvic Organ Prolapse Surgery

- The **absence** of recurrent prolapse **symptoms** influences patient satisfaction greater than the elimination of anatomic prolapse.
- It is vital to understand the patients’ goals and expectations of surgery and carefully review the risks and benefits of each surgical approach.
- Postoperative “events,” such as catheterization or urinary tract infection, are significant to the patient and negatively influence perception of outcomes.
- The preoperative informed consent is a good time to review the patient's goals and expectations as well as discuss the risks and benefits of each surgical option.
- It is important for the patient to be educated on what to expect throughout the perioperative course, because patients may perceive perioperative events as “complications,” having a negative impact on the overall perception of the procedure.

Use of Mesh in Vaginal Surgery: Current Controversy

The high failure rates of POP and stress urinary incontinence (SUI) surgery have long been recognized (Olsen et al., 1997). Because of inherent connective tissue defects that contribute to SUI and POP, surgeons have long sought after materials that may augment repairs and result in more durable outcomes. Biologic materials have been used but unfortunately have had inconsistent results because of variability of graft function. With the use of mesh as a graft in prolapse surgery, there are differences in volume of mesh, sites of mesh implantation, amounts of vaginal dissection, and surgical expertise required to perform these procedures competently when compared with mesh for SUI. Based on the enormous success of the mid-urethral sling (MUS), the US Food and Drug Administration (FDA) granted more than 100 510K exemptions for mesh “kits” to be used in the surgical management of POP (FDA, 2013). With use of the initial technique of transobturator access, the trocars and mesh grafts were modified to facilitate multi-compartment POP repair. This resulted in larger grafts being inserted or tunneled to the sacrospinous ligament (SSL), iliococcygeus fascia, arcus tendineus, obturator internus, the levator ani, and the perineal body. To accomplish this, considerably more vaginal dissection through wider incisions is required. Wider vaginal flaps can be more prone to “breakdown,” resulting in mesh exposure. Fluid accumulation or bleeding from deep dissection and tension or buckling of the mesh sheets may adversely affect graft incorporation leading to an exposure, erosion, or pain. Tacking or tunneling of larger volumes of mesh into the deep pelvic musculature may lead to neuromuscular dysfunction of the levator ani complex and subsequent pelvic floor dysfunction. Last, some surgeons who were not performing transvaginal tissue-based prolapse repairs may have started performing these procedures as an “extension” of the transobturator technique. It is very clear that much more advanced dissection skills and techniques are required to perform a mesh-based prolapse repair versus an MUS. There is no doubt that a number of high-volume, accomplished vaginal surgeons are performing mesh-based prolapse repairs safely on their patients (Murphy et al., 2012). However, it is not all just about experience of the surgeon. The volume, techniques of dissection, and location of the mesh for POP repairs are associated with a risk profile much greater than the

MUS, and these procedures are vastly different, even with the same type of mesh.

Outcomes data comparisons also reveal disparity between these two procedures. With the first-generation MUS, the efficacy and safety has been demonstrated worldwide through multiple studies with little dispute (Togami et al., 2012). Thus these procedures are a clear (and often preferred) option in the surgical treatment of SUI. The same cannot be said for POP repairs. Most would agree that anatomic outcomes appear better in the anterior compartment (Maher et al., 2013). However, the data are less compelling in the posterior compartment and apex. When subjective outcomes and reoperation rates are included, the data regarding mesh for prolapse are less clear, distinctly opposite from the first-generation MUS (Togami et al., 2012). Thus the precise indications for transvaginal mesh for prolapse are much less clear.

A public health notification is an important message from the FDA Center for Devices and Radiological Health to the health care community (Schultz, 2008). This message describes a risk associated with the use of a medical device and provides recommendations to avoid or reduce the risk. In October of 2008, the FDA released a public health statement: “Serious Complications Are Associated with Transvaginal Placement of Surgical Mesh in Repair of Pelvic Organ Prolapse and Stress Urinary Incontinence.” This report was designed to alert health care practitioners of complications associated with transvaginal placement of surgical mesh to treat POP and SUI. This report cited that over 3 years, the FDA received more than 1000 reports from nine surgical mesh manufacturers of complications that were associated with surgical mesh devices used to repair POP and SUI. As a result, a number of recommendations were made to physicians, which included obtaining specialized training for each mesh placement technique and informing patients that implantation of surgical mesh is permanent. It was also recommended to inform patients about the potential for serious complications and adverse effect on their QoL. As part of this notification, the FDA embarked on additional investigations into MUS and POP procedures using mesh, which resulted in an update of the public health notification in 2011 (Togami et al., 2012). This update was to inform the public once again regarding serious complications related to the use of transvaginal mesh in pelvic organ prolapse. **The 2011 notification was regarding POP only and did not include SUI** (Togami et al., 2012). In 2013 the FDA released additional findings regarding the use of mesh for SUI and POP (Togami et al., 2012). On the subject of mesh for SUI, the FDA concluded that “the safety and effectiveness of multi-incision slings is well-established in clinical trials that followed patients for up to one-year. Longer follow-up data is available in the literature, but there are fewer of these long-term studies compared to studies with one-year follow-up." They also concluded that "mesh sling surgeries for SUI have been reported to be successful in approximately 70 to 80 percent of women at one year, based on women's reports and physical exams…and the vaginal exposure of mesh occurred in 2% of cases" (Togami et al., 2008).

This is clearly different than the conclusions regarding the use of transvaginal mesh for POP, in which the FDA concluded that the complications are not rare and are of serious concern, and that there is no clear benefit to using mesh in the transvaginal correction of POP. These conclusions led the FDA to recommend changing the classification of transvaginal mesh to Class III devices, require extensive premarket testing on any new mesh kits for prolapse, and require 522 post-market surveillance studies compared with tissue-based repairs to demonstrate safety and efficacy of transvaginal mesh for prolapse. During this period, any prolapse kits using mesh currently available can still be used by surgeons. In contrast, the FDA did not reclassify transvaginal mesh for the sling in the treatment of SUI. No premarket data or post-market 522 data will be required for the first-generation MUS procedures (retropubic and obturator) (Togami et al., 2012). **Based on these observations, it is clear that the FDA concluded that the benefit-risk ratio of the first-generation MUS was clearly favorable and did not recommend any alteration of its use.** To be clear, the FDA did require post-market 522 studies of the second generation mini-slings because of concerns that these procedures have inferior efficacy compared with retropubic or transobturator slings (Togami et al., 2012). In 2016 the FDA reclassified the trocars used in mesh procedures to a Class II device. These are the instruments used to place the mesh only, and this reclassification did not change the previous recommendations for vaginal mesh in any way.

Subsequently, a plethora of legal actions have occurred based on the FDA activity regarding vaginal mesh. Multiple class action lawsuits have been organized against the manufacturers of mesh used for the treatment of SUI *and* POP. Millions of dollars have already been awarded, and this figure will likely rise exponentially. Several large companies have decided to withdraw their mesh products for POP from the marketplace. There is an infiltration of the media regarding class action lawsuits against mesh manufacturers, which has resulted in a global negative bias regarding mesh for the treatment of SUI and POP. Some of these advertisements contend that the mesh is "defective" and has been “recalled.” These claims are not congruent with the FDA findings and have also created concern in many women who have been successfully implanted with vaginal mesh, seeking removal of the “defective mesh.”

There has been no recall or clinical evidence of defective mesh. In fact, the FDA actions of allowing continued use of these products while undergoing post-market surveillance demonstrates that the FDA did not conclude that these products are defective. Also, the continued inclusion of the MUS in these advertisements is in direct opposition to the FDA findings and level I evidence through NIH-sponsored clinical trials, which demonstrate that MUS procedures are safe and effective.

So where does this leave clinicians of today? We are in an environment of having to deal with the realities of POP and SUI QoL disturbances and recurrences after native tissue repair in our patients who are now anxious and likely have a very negative bias against mesh. These realities exist with almost nonexistent high-quality, comparative evidence in the area of POP. What can we do to appropriately counsel and guide our patients through surgical procedures best for them? It is pretty clear that these answers do not exist, and comparative trials as well as registries are desperately needed to guide us through this process.

In an effort to aide surgeons, the following recommendations are offered with the goal of safe, judicious POP surgery:

- **Patients should be counseled extensively regarding the mesh procedure(s) recommended, including MUS procedures.** They should be informed that they are getting mesh (and why it is best for them), that there are non-mesh alternatives, and that there are complications that do occur that are unique to mesh. They should be informed that these complications may be permanent and may require more than one operation, which may or may not correct the problem. Patients should also be informed that the most common complication unique to mesh is mesh exposure, which may be asymptomatic or require a surgical revision, which may usually address the problem.
- **Clinicians should refer patients to the manufacturer's website regarding the specific procedure for them.** They

should be encouraged to learn more about their procedure in advance of the surgery. **Clinicians should refer patients to the FDA website regarding the FDA Vaginal Mesh Communication** and to the websites of the subspecialty societies *(American Urologic Association and the Society for Urodynamics, Female Pelvic Medicine and Urogenital Reconstruction),* which contain consensus statements and other links regarding vaginal mesh.

- **Clinicians should maintain the strong distinction between MUS procedures (retropubic and obturator) and transvaginal mesh procedures for POP**. Patients should be informed of the FDA actions that were vastly different between the two procedures and that there is prospective NIH research demonstrating the safety and efficacy of the MUS. Although the litigation involves all procedures, patients should be informed that the currently available evidence demonstrates the safety and efficacy of the MUS, making it the standard surgical treatment for SUI.
- **Widespread, routine use of transvaginal mesh, particularly on primary procedures, should be discouraged in patients with POP. In the current environment, the majority of POP mesh prolapse kits have been removed from the US market. In addition, several countries (UK, New Zealand, and Australia) have essentially removed transvaginal mesh for prolapse as an option for nearly all patients** (Polypropylene vaginal mesh implants for vaginal prolapse, 2007)**. In the current environment it is not recommended for surgeons with lesser degrees of experience in prolapse surgery to embark on these procedures.**
- Because the current evidence of transvaginal mesh for POP is much more limited and the indications far less clear, the American Urogynecologic Society (AUGS) position statement advocates for only experienced, credentialed surgeons to implant

mash vaginally for prolapse, and that in very special circumstance, mesh may be considered in highly select patients (AUGS, 2018).

- **Surgeons should be vigilant in assessing patient complaints.** Patients must be reassured that any postoperative concern is not "dismissed." Surgeons should directly address these concerns and offer assistance in second-opinion referrals in the absence of an explanation. With the current uncertainty and negative perceptions of mesh patients need reassurance that their concerns are adequately addressed and reasonable attempts are being made to address them.
- **Surgeons should endorse and participate in prospective, comparative clinical trials as well as registries to advance the knowledge of and identify best practices of transvaginal mesh usage.**

A summary of FDA activity regarding vaginal mesh is presented in Table 124.1.

TABLE 124.1

Summary of FDA Activity Regarding Vaginal Mesh

2002: FDA clearance of surgical mesh for POP • Approval via FDA 510(k) Clearance Process–POP RX considered substantially equivalent to mesh for SUI and hernia repairs
2008 Public Health Notification regarding safety of transvaginal mesh for POP and SUI
2011: FDA Update on Serious Complications Associated With Transvaginal Placement of Surgical Mesh for Pelvic Organ Prolapse (slings not mentioned) • Complications with POP kits "not rare" • Full-incision sling at 1 year appear "effective"
2014: 513(e) FDA order to reclassify POP vaginal mesh to class III
2016: Reclassify instrumentation from class I to class II

Surgical Management of Pelvic Organ Prolapse

Anterior Compartment

Anterior Colporrhaphy

Kelly (1913) first described his method of cystocele repair as a treatment for urinary incontinence. He emphasized the importance of repairing the pubocervical fascia with plication sutures to repair the central defect in the anterior vaginal wall. This procedure, now known as the anterior colporrhaphy or native tissue cystocele repair, remains a treatment of anterior prolapse. The use of this procedure for the treatment of incontinence diminished after the American Urological Association Female Stress Urinary Incontinence Clinical Guidelines Panel meta-analysis, which published a failure rate of nearly 40% (Leach et al., 1997).

Anterior compartment defects are commonly combined central and lateral defects (Fig. 124.1). Thus an anterior colporrhaphy, which corrects only central compartment defects, usually must be combined with a paravaginal repair or lateral anchoring for the treatment of anterior wall prolapse. Isolated central defects are rare, and in these instances a colporrhaphy alone may suffice. The early series on anterior colporrhaphy for the treatment of anterior vaginal wall prolapse reported objective success rates of 80% to 100% (Macer, 1978; Porges and Smilen, 1994; Stanton et al., 1982; Walter et al., 1982). Weber et al. (2001) in a randomized trial of three surgical techniques reported a 70% failure rate of native tissue anterior repairs. Recent re-analysis of this data set, using a more contemporary and agreed-upon definition of failure (prolapse beyond the hymen), reports a significantly better anatomic outcome with only 10% of patients experiencing prolapse beyond the hymen and only 5% of patients reporting prolapse symptoms (Chmielewski et al., 2011). The extreme differences in failure rates for anterior colporrhaphy seen in the literature can be explained primarily by the variability in definition of failure and the fact that in early series these procedures were performed in patients with multiple defects.

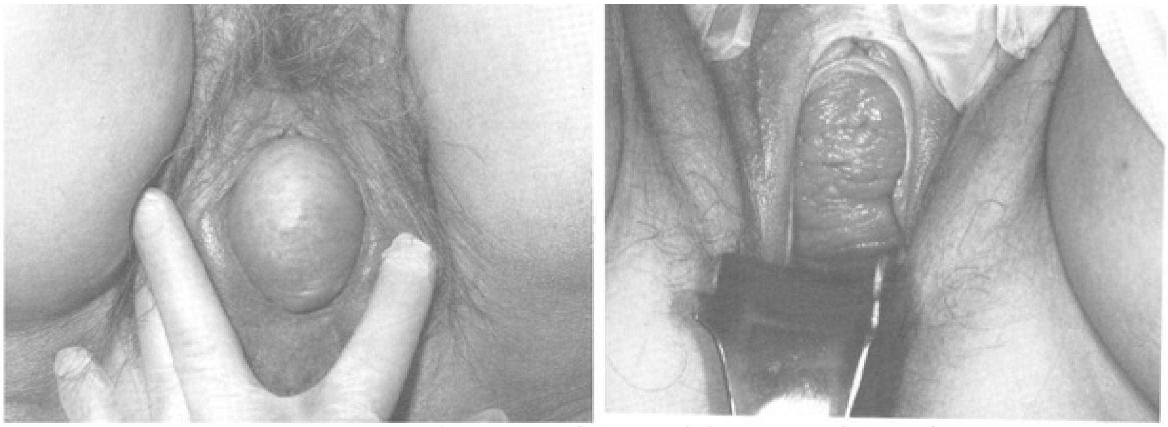

FIG. 124.1 Cystoceles. *Left,* Central defect. *Right,* lateral defect. (From Baggish M, Karram M: *Atlas of pelvic anatomy and gynecologic surgery,* ed 3, Philadelphia, 2010, Elsevier, p 645, Fig 53-3, 53-4.)

Anterior Colporrhaphy Technique (Fig. 124.2).

The patient is placed in the dorsal lithotomy position with all pressure points padded and the hip and knee joints flexed approximately 90 degrees. Fixed or handheld retraction can be helpful and generally depends on patient body habitus as well as availability of surgical staff for assistance. An indwelling urethral catheter is placed and the bladder is drained continuously throughout the procedure. Hydrodissection may be used to facilitate the dissection. A midline incision is made in the anterior vaginal wall, extending from the vaginal apex to the bladder neck. The incision should not extend to the urethra when a simultaneous MUS is anticipated. Optimally, the sling should be placed through a separate, mid-urethral incision. However, in performance of a pubovaginal sling, it is desirable to create one incision that extends from the vaginal apex to the mid-urethra to facilitate more precise sling positioning over the bladder neck. The vaginal wall is dissected off the pubocervical fascia starting in the midline and advancing laterally beyond the pubic rami. This dissection should allow sufficient visualization to delineate central and lateral defects. Allis clamps or a self-retaining ring retractor may be used to provide optimal exposure. The bladder is then reduced with a finger or instrument to facilitate lateral exposure and reapproximation of the lateral pubocervical tissues in the midline. Interrupted 2-0 or 3-0 delayed absorbable plication sutures are placed from the bladder neck to the apex in a sequential fashion. The plication sutures are then tied as the assistant reduces the prolapsed tissue. Care must be taken to avoid excessively deep suture placement that may penetrate the bladder or ureteral lumens or kink the distal ureters or intramural tunnels. Augmented repairs use allograft or mesh to reinforce the plication sutures (see the later discussion of augmented repairs). Excess anterior vaginal wall may be judiciously trimmed, and the anterior vaginal wall is closed with absorbable suture in a running fashion. After completion of the repair, indigo carmine or methylene blue is administered and cystoscopy is performed to inspect the bladder for iatrogenic injury and to visualize ureteral patency. Vaginal packing may be used to cover the surgical area and assist with hemostasis.

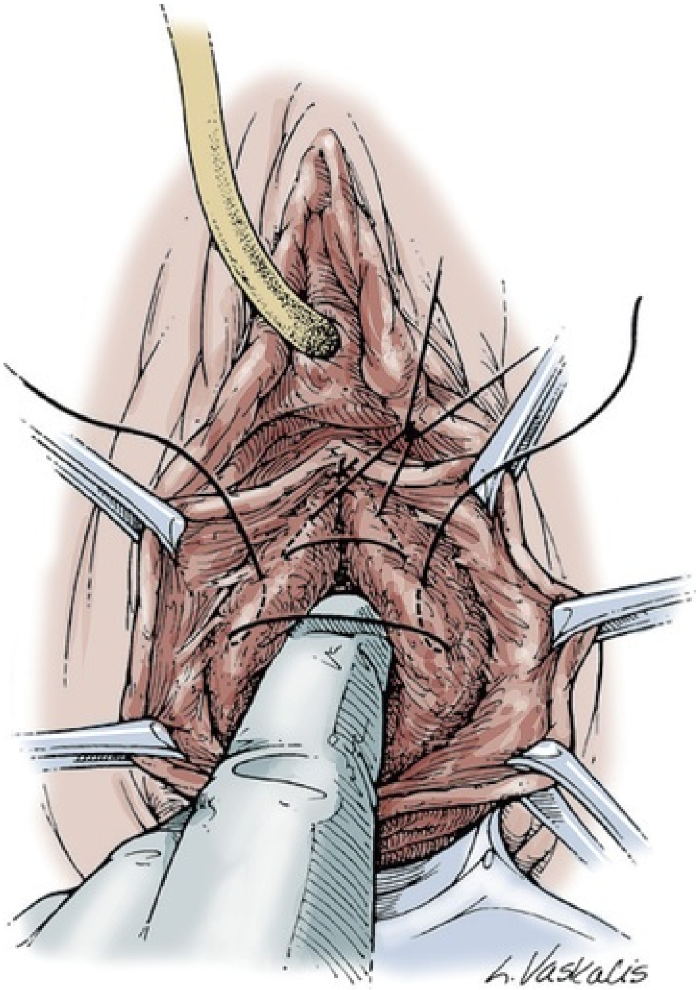

FIG. 124.2 Anterior colporrhaphy. The anterior fibromuscularis layer is imbricated with 2-0 delayed absorbable continuous or interrupted suture. (From Nicholas DH: Cystocele. In Nichols DH, editor: *Gynecologic and obstetric surgery,* St Louis, 1993, Mosby, pp 334–362.)

Anterior Colporrhaphy Repairs Results.

In earlier studies, the reported cure rate of anterior colporrhaphy was high (Table 124.3). In a large retrospective study looking at 299 patients with anterior vaginal wall prolapse, Porges and Smilen (1994) reported a recurrence rate of only 3%, with a mean follow-up of 31 months. In a prospective, randomized trial between Burch colposuspension and anterior colporrhaphy, Colombo et al. (2000) reported a recurrence rate again of only 3% in the 33 patients who underwent anterior colporrhaphy with a mean follow-up of 5 years. In contrast a retrospective secondary analysis study comparing anterior colporrhaphy alone to anterior colporrhaphy plus sling, anterior prolapse was noted in 42% of those who underwent anterior colporrhaphy alone versus 19% of those who had concomitant sling (Goldberg et al., 2001). In **series comparing anterior colporrhaphy with augmented repairs, reported recurrence rates for standard anterior colporrhaphy approach 40%, significantly higher than the earlier recurrence rates** (Table 124.4). Sand et al. (2001) reported on 161 women randomized to anterior colporrhaphy with polyglactin 910 (Vicryl) suture alone or anterior colporrhaphy with a free Vicryl mesh inlay placed under the trigone after plicating the pubocervical fascia. At 1 year, the women with Vicryl mesh inlay had a failure rate of 25% compared with 43% in women who underwent plication with suture alone (*P* = 0.02).

Weber et al. (2001) compared anterior colporrhaphy reinforced with Vicryl mesh to traditional plication without tension using polydioxanone suture and “ultra-lateral” plication using polydioxanone suture and tension. In this study, 114 women with symptomatic cystoceles (mostly stages 2 and 3 on the pelvic organ prolapse-quantification [POP-Q]) were randomized among the three groups. With a mean follow-up of 23 months, there was no significant difference in failure rate (defined as stage 2 or greater on the POP-Q) among the three groups. The failure rate was 30% in those who underwent traditional plication, 46% in those who underwent ultra-lateral plication, and 42% in those who underwent traditional plication augmented with Vicryl mesh. Unfortunately, the study did not recruit enough women to achieve statistical power to detect differences among the groups. The results of this study still suggest, however, that there does not seem to be an advantage of one suturing technique over another for anterior colporrhaphy in terms of anatomic or symptomatic relief. As noted earlier, recent re-evaluation of the Weber dataset from 2001 revealed significantly better outcomes when applying failure as recurrent prolapse beyond the hymen (Chmielewski et al., 2011). Failure rates at 1 year were 11% in the traditional plication group, 23% in the ultra-lateral group, and 9% in the mesh augmented group, adding up to a combined objective recurrence rate of 12% with no statistically significant difference among groups. **Before the re-evaluation of this data, concern over high recurrence rates and lack of durability with anterior colporrhaphy led investigators to explore augmented repairs using biologic and non-biologic sources. A 2017 long-term follow-up study of 114 patients randomized to anterior colporrhaphy or ultra-lateral colporrhaphy with dermal graft found that after 7 to 10 years there was no statistical difference in success rates** (Iyer et al., 2018)**. However, a 2016 Cochrane review led by Maher looking at 33 trials composed of 3332 women concluded that biologic graft repair or absorbable mesh provides minimal advantage when compared with native tissue repair** (Maher et al., 2016b)**. They also found that native tissue repair was associated with increased awareness of prolapse and increased risk of repeat surgery for prolapse, as well as recurrence of anterior compartment prolapse, when compared with polypropylene mesh.**

Anterior Colporrhaphy Complications.

Reported complications from anterior colporrhaphy include de novo or occult SUI, de novo overactive bladder symptoms, postoperative urinary retention, incomplete bladder emptying, significant bleeding exceeding 350 mL, wound infection, bladder or ureteral injuries, vesicovaginal fistula, vaginal shortening, epithelial inclusion cyst, and dyspareunia. **De novo detrusor overactivity** can also occur in 5% to 7% of patients after standard colporrhaphy (Raz et al., 1991). Yet, **preexisting detrusor overactivity has also been reported to resolve in up to 63% of patients after surgical repair of POP** (Nguyen and Bhatia, 2001). In a secondary analysis of the Colpopexy and Urinary Reduction Efforts (CARE) trial, Davenport et al. (2017) found the incidence of de novo SUI after prolapse repair directly correlates to the degree of cystocele on preoperative examination. The incidence of de novo SUI based on the POP Quantification stage of anterior prolapse was 41.3%, 52.5%, and 66.1%, for stage 2, early stage 3, and advanced stage 3 or stage 4, respectively. Furthermore, point Ba was found to be significantly associated with de novo SUI on univariate (odds ratio [OR] = 1.17, $P = 0.015$) and multivariate analysis (OR = 1.16, $P = 0.04$). Urinary retention usually occurs in cases during which a concomitant anti-incontinence procedure was performed; however, retention or incomplete emptying may occur in the absence of anti-incontinence surgery and may be the result of neurologic trauma and impaired bladder contractility from the plication procedure. In most instances, the retention resolves after a brief period of clean intermittent catheterization (CIC). If the retention persists and the patient had a concomitant anti-incontinence procedure, a sling incision or urethrolysis may be required. When impaired bladder emptying is due to preexisting hypocontractility, the patient may require chronic CIC, neuromodulation, or, as a last resort, suprapubic tube drainage.

Bleeding during anterior colporrhaphy is usually due to the high vascularity of the vagina and to the venous complex beneath the inferior pubic bone. **During anterior colporrhaphy, problematic bleeding can occur if the dissection is carried out in the wrong plane. The vaginal wall should be dissected from the pubocervical fascia directly on its white, shiny surface.** In patients undergoing repeat anterior colporrhaphy, scarring often obscures the correct dissection plane. As such, these patients are at higher risk for bleeding.

Bladder or ureteral injuries are rare during standard anterior colporrhaphy. **Bladder injuries can occur when perforating into the retropubic space or during dissection of the vaginal flaps, especially in women with atrophic tissue. Ensuring proper bladder drainage before perforating the endopelvic fascia may reduce this.** Should an inadvertent bladder injury occur, a two-layer closure should be performed with absorbable suture. If the patient has a history of pelvic irradiation or if the repair quality seems tenuous, a labial fat pad interposition should be considered to prevent vesicovaginal fistula formation (Kreder, 1993). **Cystoscopy after the administration of indigo carmine should be routinely performed with every anterior colporrhaphy. If blue-stained urine is not seen effluxing from both ureteral orifices, ureteral catheterization, retrograde pyelography, or release of the plication sutures should be performed.** In some cases the ureter is patent, and an alternative reason, including inadequate fluid resuscitation or ureteral kinking, will explain the lack of efflux. Appropriate steps must be taken to ensure ureteral patency if the ureter cannot be catheterized.

Procedures for Lateral and Combined Defects

Vaginal Paravaginal Repair.

In his first description of a vaginal paravaginal repair, George White described a cystocele repair that involved suturing the lateral sulci of the vagina to the white line of the pelvic fascia in 1909 (White, 1997). White believed that the cause of a cystocele was weakness of the lateral vaginal attachments to the arcus tendineus fascia pelvis (ATFP). As Kelly's anterior colporrhaphy became the primary technique of cystocele repair for the next 70 years, White's concept fell into disfavor. In 1976 Richardson et al. reintroduced the paravaginal defect repair (PVdR), but he described the technique using an abdominal approach. Regardless of the approach, **the goal of a paravaginal repair is to repair a lateral compartment defect by reattaching the pubocervical fascia to the ATFP**. **A vaginal paravaginal repair may be combined with anterior colporrhaphy in patients with combined lateral and central defects.**

Technique (Fig. 124.3).

A midline vertical incision is made through the anterior vaginal wall from the bladder neck to the vaginal apex. After the vaginal wall is sharply dissected off the attenuated pubocervical fascia and bladder, the dissection is carried laterally to the pelvic sidewall. Blunt dissection can be used to facilitate this. Access to the pelvic sidewall is achieved by continued lateral dissection and perforation of the endopelvic fascia. Upon entry into the retropubic space, palpation is used to identify the ATFP as it courses from the ischial spine to the inferior aspect of the pubic ramus. Deep, lighted retractors may be useful to facilitate exposure. With the bladder retracted medially, multiple interrupted nonabsorbable sutures are placed at 1-cm intervals through the ATFP. A Capio Suture Capturing Device (Boston Scientific, Marlborough, MA) needle driver device may expedite placement of these sutures. We prefer the Capio Slim (Boston Scientific, Marlborough, MA). These sutures are then passed through the lateral edge of the detached pubocervical fascia. No sutures should be tied until all are placed on either one side or both sides (if bilateral defects). At this point, if indicated, central defect plication sutures may be placed to complete a combined repair. As with anterior colporrhaphy, cystoscopy must be performed to confirm ureteral patency and the absence of intravesical sutures. The vaginal wall is trimmed judiciously, if needed, and closed with a 2-0 absorbable suture. Vaginal packing is placed at the end of the case.

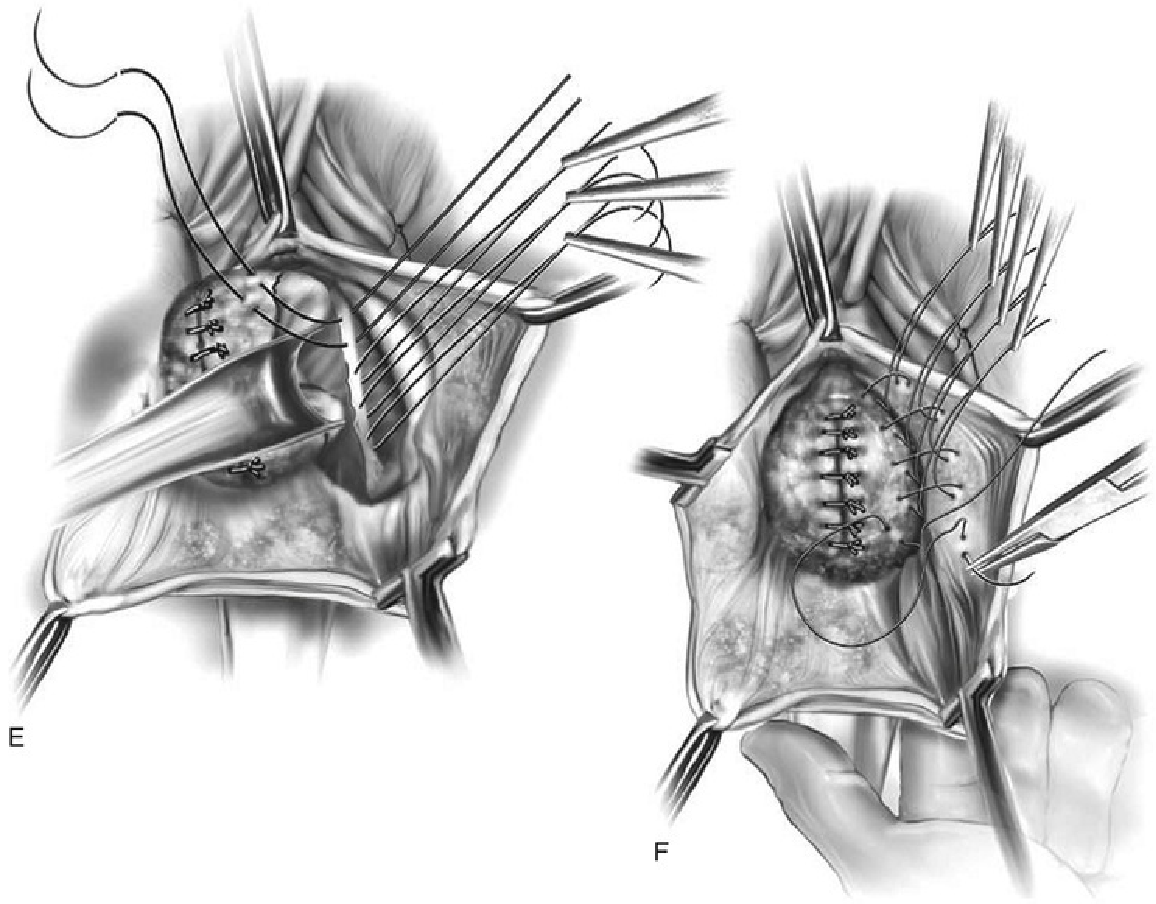

FIG. 124.3 Vaginal paravaginal repair. (A) Unopened anterior vaginal wall with marking sutures placed at anatomic level of bladder neck and vaginal apex. (B) Anterior vaginal wall opened via a midline incision. Sutures placed for midline cystocele repair. (C) Midline cystocele repair completed. Bilateral paravaginal defects identified. (D) Bladder retracted medially to expose lateral pelvic side wall. Permanent sutures have been passed through the white line. (E) Top two sutures have been passed through the detached edge of pubocervical fascia. (F) Three-point closure is completed with all sutures passed through the pubocervical fascia and inside wall of the vagina. (From Baggish M, Karram M: *Atlas of pelvic anatomy and gynecologic surgery,* ed 3, Philadelphia, 2010, Saunders.)

Vaginal Paravaginal Repair Results (See Table 124.3).

Shull et al. (1994) reported successful repair without any evidence of prolapse 73% of 41 patients after a mean follow-up of 1.6 years. Of the 15 recurrences, only 4 developed prolapse to or through the hymen, and in these 4 the prolapse was less than what was noted preoperatively. Grody et al. (1995) reported a 99% success rate in 72 patients 0.5 to 3 years after vaginal paravaginal repair. Elkins et al. (2000) reported an 8% lateral cystocele recurrence rate and a 22% central cystocele recurrence rate 0.5 to 3 years after vaginal paravaginal repair in 25 patients with grade 3 or greater anterior wall vaginal prolapse. Midline central defects were common, leading surgeons to perform joint repairs with an anterior colporrhaphy. Young et al. (2001) retrospectively evaluated 100 patients with symptomatic grades 2 to 4 combined central and lateral cystoceles. All 100 patients underwent vaginal paravaginal repair and concomitant anterior colporrhaphy. With a mean follow-up of 11 months, the lateral cystocele recurrence rate was only 2%, and the central cystocele recurrence rate was 22%. Mallipeddi et al. (2001) reported a 3% central cystocele recurrence 20 months after vaginal paravaginal repair in 35 patients with grades 2 to 4 anterior vaginal wall prolapse. Of the 21 patients with concomitant SUI, 12 (57%) had persistent SUI after the paravaginal repair. **The paravaginal repair, like standard anterior colporrhaphy, is ineffective in the treatment of SUI.**

A retrospective analysis of patients undergoing anterior colporrhaphy alone versus anterior colporrhaphy plus paravaginal defect repair reports no statistically significant differences between the groups in either subjective or objective outcome measures (Morse et al., 2007).

Although complications after vaginal paravaginal repair are infrequent, they are significant. Young et al. (2001) reported 21 major complications, including 3 major intraoperative hemorrhagic complications. Two patients developed lower extremity neuropathy; one was in the lithotomy position for a prolonged period of time. Elkins et al. (2000) reported a transfusion rate of 12%. Mallipeddi et al. (2001) reported 2 patients with vaginal abscesses that required drainage, 1 patient with retropubic hematoma who required re-exploration, and 1 patient with bilateral ureteric obstruction, which resolved after takedown of the repair and suture replacement.

The vaginal paravaginal repair as described is technically more challenging than the standard anterior colporrhaphy. Complication rates are higher and usually more serious. In addition, the conventional vaginal paravaginal repair relies on suture placement through weakened pubocervical fascia. To compensate for these factors, most surgeons describe transvaginal correction of lateral defects using placement of grafts, which are attached to the pelvic sidewalls bilaterally.

Anterior Compartment Repairs Using Grafts Technique

The incision and dissection into the retropubic space are carried out in a similar manner as in the vaginal paravaginal repair. Once access to the pelvic sidewall is achieved, the bladder is retracted medially, and 2 or more sutures (permanent or delayed absorbable) are placed into the arcus tendineus fascia pelvis and/or obturator internus fascia, which will serve as adequate lateral fixation for the graft. The graft material may also be anchored distally to the bladder neck and apically to the cervix, bladder, or vaginal wall. A Capio Suture Capturing Device (Boston Scientific, Marlborough, MA) may expedite placement of these sutures (Fig. 124.4). Before the graft is fashioned, it is useful to estimate the distance between the proximal and distal ipsilateral sutures and the distance between the sutures on each side. These measurements determine the dimensions of the graft material, which is trimmed to size. At this point, central plication sutures may be performed. The previously placed pelvic sidewall sutures are then brought out to the corresponding locations on the graft. The sutures are then tied, securing the graft to the pelvic sidewall. It is useful to leave the sutures long until after cystoscopy confirms patency of the ureters. The vaginal wall is judiciously trimmed, if needed, and closed with a 2-0 absorbable suture. Vaginal packing is placed at the end of the case.

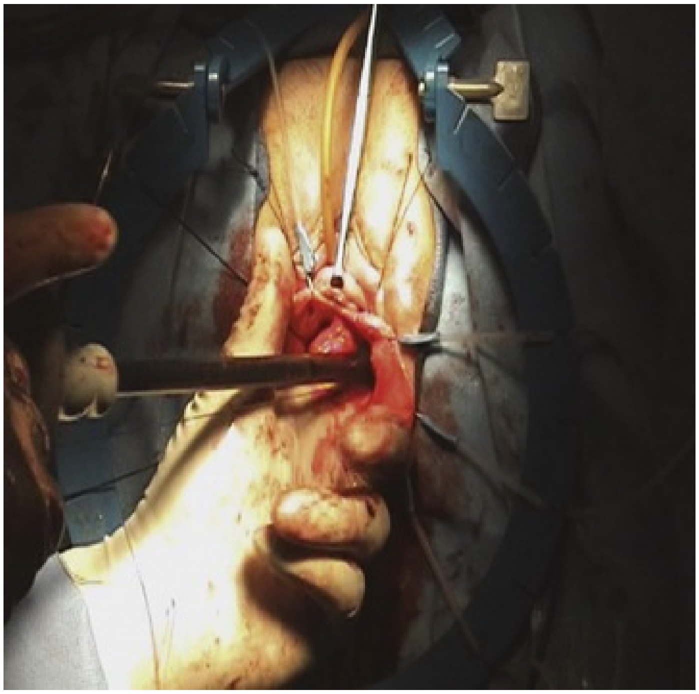

FIG. 124.4 Capio needle driver used to facilitate suture placement in the arcus tendineus fascia pelvis. (Courtesy Victor Nitti.)

Anterior Polypropylene Mesh Results

Nicita (1998) described the use of polypropylene mesh for the treatment of anterior vaginal wall prolapse (see Table 124.4). He sutured the mesh to the anterior aspect of the arcus tendineus fascia pelvis on each side using 3-0 Prolene sutures. With 2 years of follow-up, only 3 of the 44 patients (7%) had prolapse recurrence. The only patient that developed dyspareunia had vaginal mesh extrusion (exposure), and this was managed with mesh trimming and vaginal closure. Several subsequent studies using polypropylene mesh reported variable success ranging from 76% to 98% (de Tayrac et al., 2002, 2005, 2006; Salvatore et al., 2002; Sivaslioglu et al., 2008). de Tayrac et al. in 2002 described placement of polypropylene mesh (Gynemesh, Ethicon) into the retropubic space in a tension-free fashion without suture fixation. The lateral extensions of the mesh were placed in contact with the arcus tendineus fascia pelvis and anchored with a transobturator approach. A total of 48 women with grade 3 and 4 cystoceles underwent this procedure. After a mean follow-up of 18 months, the authors reported an anatomic success rate of 97.9%. Vaginal mesh extrusion was noted in 8.3%. In a subsequent series with 87 women and with 24 months of follow-up, de Tayrac again used Gynemesh and found that 77 women (88.5%) were cured of their symptomatic anterior vaginal wall prolapse, defined as POP-Q stage 0 or 1 (de Tayrac et al., 2005). Of the 7 patients with recurrent cystoceles, 5 were asymptomatic. Vaginal mesh extrusion was again noted in 8.3%, and the de-novo dyspareunia rate was 16.7%.

In a prospective study of 98 patients with stage 3 or 4 cystoceles, Rodríguez et al. (2005) attached a 5- × 5-cm piece of polypropylene mesh to the obturator internus fascia using 2-0 polyglactin suture after repair of the central defect with horizontal mattress sutures of 3-0 polyglactin sutures **(Fig. 124.5)**. All patients underwent a distal urethral polypropylene sling regardless of any SUI symptoms. The researchers reported an 85% anatomic success rate, defined as stage 0 or 1. Three patients who did not report SUI before the procedure developed mild de novo SUI after the procedure. Overall QoL associated with genitourinary symptoms improved from 4.7 (unhappy) to 1 (pleased) ($P < 0.005$).

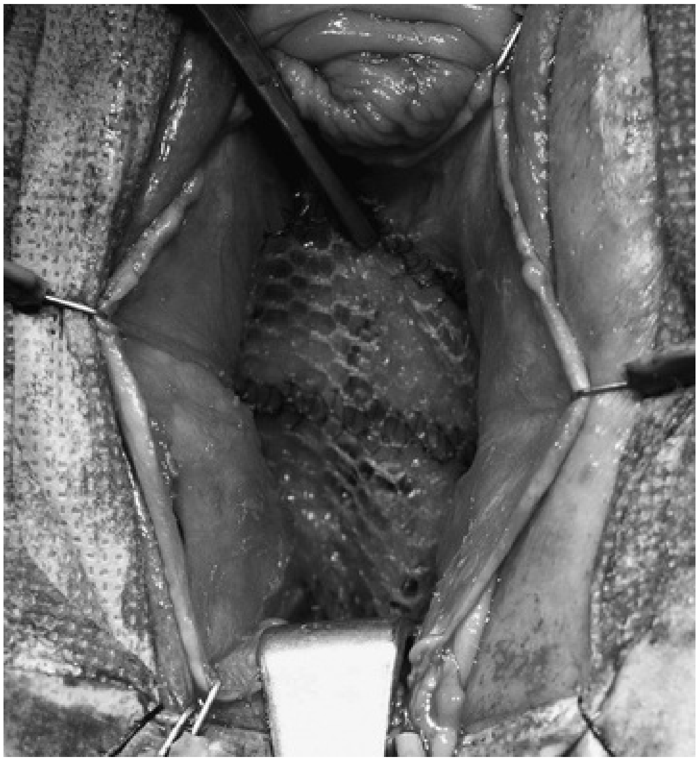

FIG. 124.5 Anterior compartment repair with polypropylene mesh graft. Polypropylene mesh is anchored to the sacrouterine ligament at the bladder base, laterally to the obturator fascia, and distal to the bladder neck using 2-0 polyglactin suture. (From Rodriguez LR, Bukkapatnam R, Shah SM, et al.: Transvaginal paravaginal repair of high-grade cystocele central and lateral defects with concomitant suburethral sling: report of early results, outcomes, and patient satisfaction with a new technique. *Urology* 66[Suppl 5A]:57–65, 2005).

Carey et al. (2009) reported on 139 women randomized to mesh augmented anterior and posterior repair versus anterior and posterior colporrhaphy. No statistical difference in outcomes was noted with either objective or subjective measures. De novo dyspareunia rates were equal in the groups. Vaginal mesh exposure occurred in 5.6%.

In a randomized controlled trial (RCT) of 202 women with anterior vaginal wall prolapse, Nieminen et al. (2010) compared anterior colporrhaphy (*n* = 97) to the same procedure reinforced with low-weight polypropylene mesh (*n* = 105) (Hiltunen et al., 2007). After 3 years of follow-up, the addition of the polypropylene mesh to the anterior repair did statistically decrease the risk of recurrent stage 2 or greater anterior prolapse. **Recurrence was noted in 14 of 105 women in the mesh group versus 40 of 97 women in the group with no graft ($P < 0.0001$). However, there was no statistically significant difference in symptomatic outcomes (pelvic pressure, vaginal bulge, or difficulty with**

bladder emptying) between the groups. Importantly, 18 patients in the mesh group (17.3%) had vaginal extrusion (exposure) of the mesh.

The 2013 Cochrane review reported that standard anterior repairs were associated with more postoperative anterior wall prolapse than polypropylene mesh repairs (relative risk [RR] 3.15; 95% confidence interval [CI] 2.50–3.96) and a higher rate of subjective failure (28% vs. 18%, RR 1.62, 95% CI 1.22–2.14) (Maher et al., 2013)**. Additional prolapse surgery was not more common in the anterior colporrhaphy group, and no differences in QoL data or de novo dyspareunia were identified. De novo SUI was greater in the mesh repair group (RR 1.8, 95% CI 1.0–3.1). The cumulative mesh erosion rate was 11.4%, and the reoperation rate to correct the erosion was 6.8%. Little has changed with this data in the 2016 Cochrane review other than concluding that the rate of de novo SUI was essentially equal between the two groups with few or no differences** (RR 0.67, 95% CI 0.44–1.01) (Maher et al., 2016b).These finding as well as an increased awareness of the severity of complications of using vaginal mesh for prolapse has led to the near abolition of the use of transvaginal mesh patch interposition or mesh kits.

Alteration of the vaginal axis with compensatory prolapse in an untreated compartment has been well reported. Development of apical and or posterior prolapse (stage 2 or greater) after an anterior repair with mesh was seen in 46% of 150 women (Withagen et al., 2010). Pooled analysis of two studies that reported de novo prolapse after anterior repair (Nieminen et al., 2010; Vollebregt et al., 2011) showed a lower rate after anterior colporrhaphy versus anterior mesh repair (9.5 vs. 17.7%, RR 0.49, 95% CI 0.24–0.97).

Anterior Repair With Cadaveric Fascia Results

Cadaveric fascia lata with or without pubovaginal sling has shown efficacy rates of 81% to 100% for the treatment of anterior vaginal wall prolapse (Frederick and Leach, 2005; Groutz et al., 2001; Kobashi et al., 2000; Powell et al., 2004; see Table 124.4). Kobashi et al. (2000) first described the cadaveric prolapse repair and sling procedure (CaPS) as combined treatment of symptomatic cystocele and SUI. The procedure was performed transvaginally using a 6- × 8-cm piece of cadaveric fascia lata and bone anchors. Groutz et al. (2001) treated 21 women with cadaveric fascia lata anchored to the ATFP bilaterally and the cardinal and uterosacral ligaments apically (Fig. 124.6). In a larger study (*n* = 251) with a mean follow-up of 2 years after CaPS, Frederick and Leach (2005) noted a symptomatic cystocele recurrence rate of only 7%. The cured or dry rate for SUI was only 56%, with most of the failures occurring beyond 1 year; the authors questioned the long-term efficacy of the sling portion of the procedure.

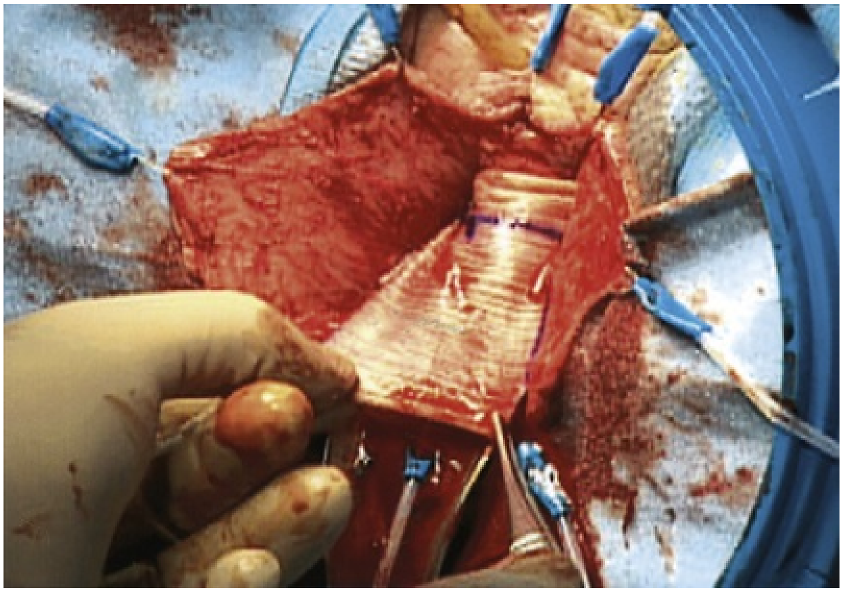

FIG. 124.6 Anterior compartment repair with cadaveric fascia graft. Cadaveric fascia patch was tailored appropriately. Typically a 5- × 7-cm patch is more than adequate. (From Groutz A, Chaikin DC, Theusen E, et al.: Use of cadaveric solvent-dehydrated fascia lata for cystocele repair—preliminary results. *Urology* 58:179–183, 2001.)

Gandhi et al. (2005) published a prospective RCT ($n = 162$) comparing ultralateral anterior colporrhaphy with 0 polyglactin suture to the same colporrhaphy reinforced with cadaveric fascia lata in women with grade 2 or greater anterior vaginal wall prolapse. The addition of the fascia lata patch to the anterior repair did not statistically decrease the risk of recurrent prolapse ($P = 0.23$). Of the 39 patients with recurrent prolapse, 26 (67%) were asymptomatic. Concomitant transvaginal Cooper ligament sling was associated with a significant decrease in recurrent prolapse (odds ratio [OR] 0.015, $P < 0.0001$).

Cadaveric dermis has been used in the treatment of anterior compartment prolapse with efficacy of 42% to 84% at 2 years of follow-up (Behnia-Willison et al., 2007; Chung et al., 2002; Clemons et al., 2003; Ward et al., 2007). Chung et al. (2002) described anchoring the proximal portion of the 3- × 7-cm graft to the uterosacral-cardinal ligament complex and the using the distal portion as the sling. Patients with lateral and paravaginal defects were excluded. Clemons et al. (2003) described a vaginal paravaginal repair using cadaveric dermis in 33 women with recurrent stage 2 or with primary or recurrent POP-Q stage 3 or 4 cystoceles. The 3- × 7-cm graft was positioned over the bladder base and secured to the ATFP with four sutures of 2-0 braided permanent polyester sutures bilaterally. **An updated 2016 Cochrane review concluded that biologic grafts provided no difference in awareness of prolapse** (RR 0.98, 95% CI 0.52–1.82) **or need for repeat surgery for prolapse when compared with traditional anterior repair** (RR 1.02, 95% CI 0.53–1.97). **Interestingly, they found that biologic grafts probably increased the risk of recurrent anterior compartment prolapse** (RR 1.32, 95% CI 1.06–1.65) (Maher et al., 2016b).

Anterior Repair With Porcine Dermis Results

The majority of clinical experience in the use of xenografts for POP has been with porcine dermis (see Table 124.4). Pelvicol (C.R. Bard) is acellular cross-linked porcine dermis (Chen et al., 2007). Gomelsky et al. (2004) reported favorable, durable outcomes using a 6- × 8-cm piece of porcine dermis sutured laterally to the ATFP to correct high-grade cystoceles (Fig. 124.7). In a retrospective review of 70 patients, 61 (87%) had no cystocele recurrence after a mean follow-up of 24 months. Of the 9 patients (13%) with recurrent cystoceles, none were symptomatic. One patient had superficial vaginal wound separation, which was treated with conservative measures.

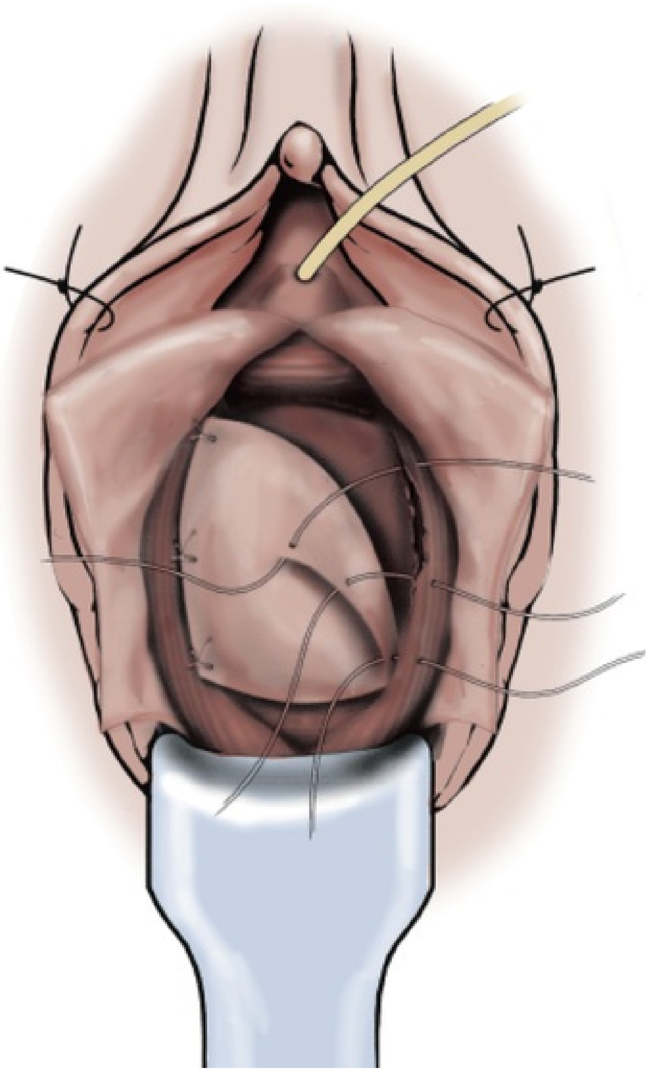

FIG. 124.7 Anterior compartment repair with porcine dermis graft. Three pairs of delayed absorbable sutures are inserted into the arcus tendineus fasciae pelvis and into the porcine dermis patch. (From Gomelsky A, Rudy DC, Dmochowski RR: Porcine dermis interposition graft for repair of high grade anterior compartment defects with or without concomitant pelvic organ procedures. *J Urol* 171:1581–1584, 2004.)

Meschia et al. (2007) published a prospective RCT comparing anterior colporrhaphy with 0 polyglactin suture (*n* = 103) versus the same colporrhaphy reinforced with a 4- × 7-cm piece of Pelvicol (*n* = 98) in women with stage 2 or greater anterior vaginal wall prolapse as defined by POP-Q. After 1 year of follow-up, the women randomized to receive the Pelvicol graft failed 7% of the time compared with the 19% failure rate in those women who underwent the anterior colporrhaphy alone (*P* = 0.019). One patient who received the Pelvicol graft had vaginal extrusion of the material 1 month after surgery. There were no differences between the 2 groups in the incidence of postoperative dyspareunia.

Handel compared two different grafts (polypropylene mesh [*n* = 25] and porcine dermis [*n* = 56]) versus traditional anterior colporrhaphy with suture alone (*n* = 18) (Handel et al., 2007). For patients undergoing repair with a graft, it was anchored to the levator fascia bilaterally and to the uterosacral-cardinal ligament complex apically. With a mean follow-up of 13.5 months, there was no significant difference in failure rate (defined as grade 2 or greater) among the 3 groups. There was a 21% rate of vaginal extrusion of the porcine dermis.

SIS has also been compared with colporrhaphy alone in an RCT (*N* = 57) (Feldner et al., 2010). The SIS group had 86.2% anatomic cure versus 59.3% in the colporrhaphy groups (*P* = 0.03). Both operations significantly improved QoL without differences noted between the groups. No infections or erosion were discovered.

Biologics Versus Mesh Results

Natale et al. (2009) performed a prospective randomized trial (*N* = 190) comparing polypropylene mesh (Gynecare) to porcine dermis (Pelvicol) in women with recurrent anterior wall prolapse. Objective cure was 71.9% in the mesh group and 56.4% in the porcine dermis group (*P* = 0.06). No difference in subjective cure was noted; however, a better impact of surgery on sexual function was reported in the porcine group. Mesh erosion occurred in 6.3% of the mesh group, and no erosion was seen with porcine dermis (*P* = 0.03).

Menefee et al. (2011) performed a randomized clinical trial comparing anterior colporrhaphy, vaginal paravaginal repair using porcine dermis, and vaginal paravaginal repair with self-styled polypropylene mesh. Two-year follow-up was completed on 78 of 99 (79%) enrolled subjects. Mesh repairs had the lowest anatomic failure rate (18%), followed by porcine (46%, *P* = 0.015), then colporrhaphy (58%, *P* = 0.002). Subjective improvement in prolapse and voiding scores were similar, and composite failure was no different among groups (4% mesh, 12% porcine, 13% colporrhaphy). Mesh erosion was reported in 14% and porcine erosion in 4% (*P* = 0.413).

A 2013 Cochrane review concluded that objective failure rates were higher with colporrhaphy alone than with the use of biologic graft (RR 2.08, 95% CI 1.08–4.01) (Maher et al., 2013). **Subjective cure rates were not different between groups. When the data was re-examined for the 2016 Cochrane review, it was seen again that objective failure rates were higher with colporrhaphy alone than with the use of polypropylene mesh** (RR 3.01, 95% CI 2.52–3.60) **or a biologic graft** (RR 1.32, 95% CI 1.06–1.65) (Maher et al., 2016b).

Mesh-Related Complications

Vaginal exposure (extrusion) has been reported in anterior compartment prolapse repair with most materials. In 21 trials on mesh-augmented repairs summarized in a Cochrane review, the mean mesh extrusion rate was 11.4% (64 of 563) with 6.8% (32 of 470) undergoing surgical intervention for the extrusion (Maher et al., 2013). **Reoperation rates for prolapse, QoL measures, and de novo dyspareunia were no different in women undergoing native tissue repair versus mesh repair** (Maher et al., 2013). **Dyspareunia has also been reported in 3.1% to 19% of patients with anterior colporrhaphy** (Dwyer and O'Reilly 2004; Milani et al. 2005; Yan et al., 2004). **Blood loss (mean difference [MD] 64 mL, 95% CI 48–81), operating time (MD 19 min, 95% CI 16–21), recurrences in apical or posterior compartment (RR 1.9, 95% CI 1.0–3.4), and de novo stress urinary incontinence (RR 1.8, 95% CI 1.0–3.1) were significantly higher with mesh repair than with native tissue repair.**

Other Procedures to Correct Anterior Compartment Defects

Abdominal Paravaginal Repair Technique (Fig. 124.8).

The patient is positioned and prepped to allow abdominal and vaginal access. The bladder is drained. The retropubic space is entered through either a low midline or transverse incision. In addition, the approach may be accomplished laparoscopically or robotically. The bladder neck, symphysis pubis, endopelvic fascia, ATFP, and obturator fascia should be clearly identified. The site of normal vaginal attachment on the pelvic sidewall from the interior aspect of the superior pubic ramus to the ischial spine is then identified. The surgeon's nondominant hand is placed into the vagina and used to elevate the lateral superior vaginal sulcus to its site of normal attachment along the course of the ATFP. With the bladder retracted medially, multiple interrupted nonabsorbable sutures are placed at 1-cm intervals through the ATFP, extending from the ischial spine to the pubic bone. These sutures are then placed in the appropriate location in the lateral wall of the vagina. Care is taken to avoid paravaginal veins, which commonly course through this area. Elevating the vagina to its normal anatomic position to localize suture placement site may facilitate vaginal suture placement. After the sutures are tied, cystoscopy must be performed to confirm ureteral patency and the absence of intravesical sutures. The incision is closed, and the catheter is left indwelling.

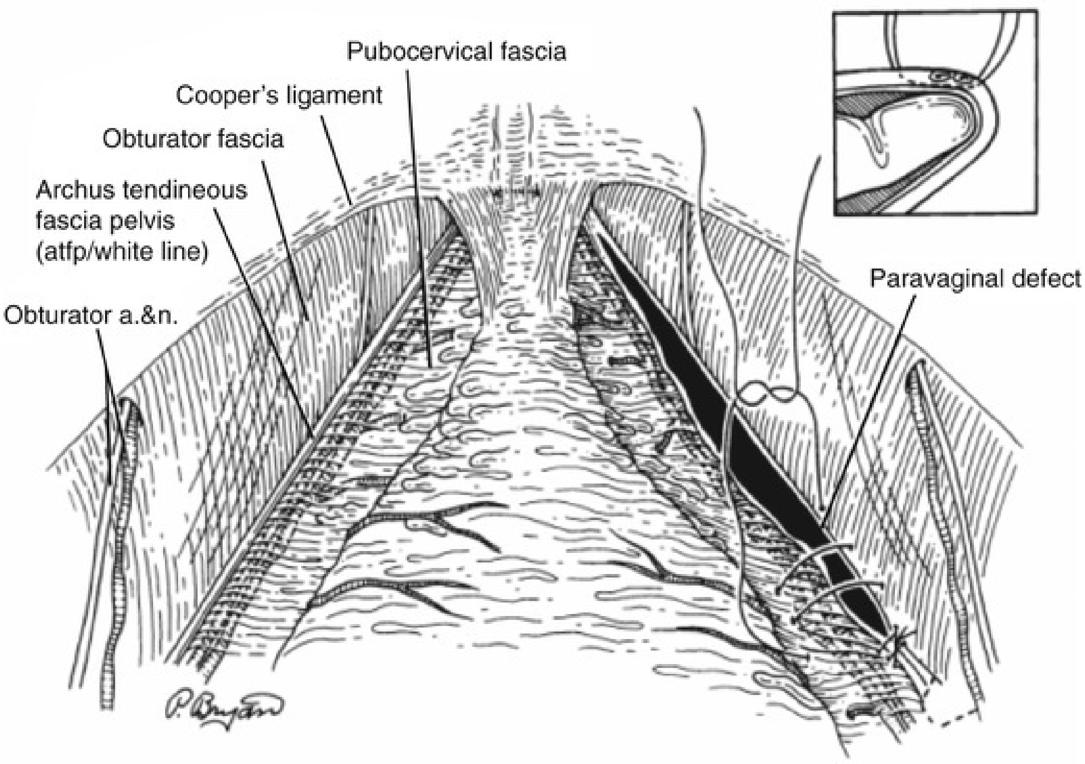

FIG. 124.8 Abdominal paravaginal repair. Paravaginal defect repair as viewed from the retropubic space: approximation of the pubocervical fascia medially to the arcus tendineus fascia pelvis laterally with 2-0 braided nonabsorbable suture. Note the vertical orientation of the vaginal vessels in relation to the transverse orientation of the bladder vessels. *Inset* shows suture being passed beneath the vaginal vessels to ensure generous purchase of pubocervical fascia and control of hemostasis. (From Bruce RG, El-Galley R, Galloway NT: Paravaginal defect repair in the treatment of female stress urinary incontinence and cystocele. *Urology* 54:647–651, 1999.)

Abdominal Paravaginal Results (See Table 124.4).

Richardson et al. (1976) popularized the abdominal paravaginal defect repair. In a retrospective study of 233 patients with follow-up spanning 2 to 8 years, Richardson et al. (1981) reported an anatomic cure rate of 95%. Of these patients, 53 (23%) had previously undergone 1 or more anterior vaginal wall prolapse repairs. No patient required transfusion. Eighty-eight percent of the women with preoperative SUI were cured after abdominal paravaginal repair.

Other authors published the results of case series that demonstrated similar encouraging anatomic results and SUI cure rates of 85% to 97% after abdominal paravaginal repair (Baden and Walker, 1987). **However, recent evidence over the last 15 years suggests that abdominal PVdR is not as effective as either the Burch colposuspension or suburethral sling for the treatment of SUI.** In 2000 Colombo et al. published the results of a randomized trial comparing PVdR with Burch colposuspension for the treatment of SUI in 18 patients. With a mean follow-up of 2.2 years, the objective (urodynamic) cure rates were 100% for Burch colposuspension and 61% for abdominal PVdR. Colombo found that Burch colposuspension increased the functional urethral length and pressure-transmission ratio in the proximal urethra, whereas the abdominal paravaginal repair did not. Bruce et al. (1999) examined the abdominal PVdR in the treatment of women with both lateral cystocele and symptomatic SUI. In this retrospective cohort of 52 patients, half underwent abdominal PVdR and half underwent abdominal PVdR with pubovaginal sling using rectus fascia. All the patients who underwent concomitant sling procedures had intrinsic sphincter deficiency (ISD). With a mean follow-up of 17 months, 4 patients (8%) had recurrent cystocele, 3 patients developed vault prolapse, and 1 patient developed an enterocele. Thus the overall prolapse cure rate was 85%. Finally, the overall cure rate for SUI was 72% in the group that underwent PVdR alone and 85% in the group that underwent PVdR and pubovaginal sling procedures. Comparing their results with abdominal and vaginal PVdR, Reid et al. (2011) found the 10-year durability was better with their abdominal approach ($N = 52$) than their vaginal approach ($N = 59$) with patients having a greater chance of remaining prolapse free in the long term (46 out of 52 [88.5%] vs. 41 out of 59 [69.5%]) (95% CI 1.029–2.708, $P = 0.038$). Interestingly no anatomic failure occurred after 38 months, inferring that site-specific repair by either route has curative potential. Symptom resolution was equivalent for all. Hosni et al. in a 2013 prospective study looked at the effectiveness of the abdominal, vaginal, and laparoscopic approaches for a PVdR. The results from 45 women found no statistical difference between the abdominal ($N = 20$) and vaginal ($N = 20$) approaches, but they had to abandon the laparoscopic ($N = 5$) approach because of the lack of improvement in prolapse stage (Hosni et al., 2013). In a 2014 RCT comparing anterior repair with vaginal mesh ($N = 35$) versus abdominal PVdR

(*N* = 35), Minassian et al. (2014) found at 2 years that success rates for both groups (<stage 2 POP) were similar, with most objective failures being asymptomatic.

Anterior Compartment Repair With Sling.

In patients with high-stage anterior compartment prolapse, the descent may create urethral kinking and urethral compression (Gallentine and Cespedes, 2001) (Fig. 124.9). This compression may prevent leakage of urine despite poor urethral function, thereby unmasking SUI after prolapse correction. Documenting the presence of SUI in patients with the prolapse reduced is helpful in the preoperative planning of women with high-stage anterior compartment prolapse. **SUI occurring in presumably continent women after prolapse correction is known as stress incontinence on prolapse reduction, formerly known as occult SUI. It is essential for women with high-stage prolapse to undergo an evaluation with the prolapse reduced to identify those are at risk for SUI.** In four prospective studies POP repair in clinically continent women was shown to result in postoperative SUI in 8.3% to 66.1% (Ballert et al., 2009; Borstad and Rud 1989; Davenport et al., 2017; Stanton et al., 1982).

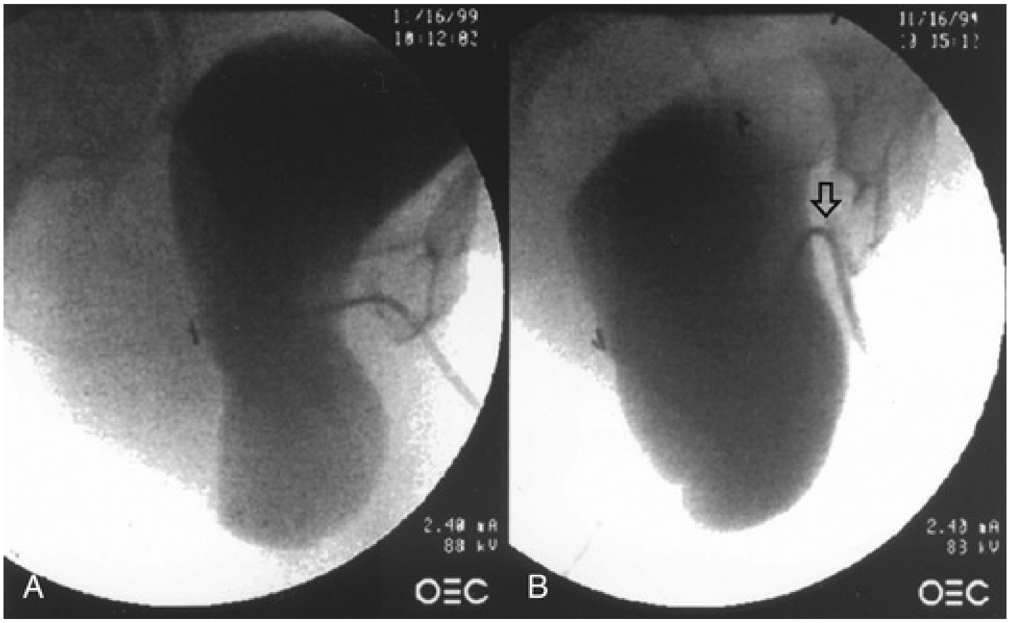

FIG. 124.9 Urethral kinking caused by large (grade IV) cystocele. Fluoroscopic imaging of the bladder demonstrating a large cystocele before (A) and after (B) Valsalva maneuver was performed. The urethra *(at arrow)* can clearly be seen to “kink” with the Valsalva. The patient did demonstrate

severe SUI after prolapse reduction. (From Gallentine ML, Cespedes RD: Occult stress urinary incontinence and the effect of vaginal vault prolapsed on abdominal leak point pressures. *Urology* 57:40–44, 2001.)

To diagnose SUI on prolapse reduction, the prolapse may be reduced with vaginal packing, rectal swabs, a speculum blade, or pessary. Ghoniem et al. (1994) used a vaginal pack (formed from two rolled 4 × 4 gauze pads) to reduce large cystoceles and found occult SUI in 69% of the women. They found that the vaginal pack provided superior visualization of the vesicourethral angle during fluoroscopic urodynamics. Gallentine used gauze packing and a speculum blade to reduce high-stage POP and found occult SUI in at least 50% of the women with high-stage anterior compartment prolapse (Gallentine and Cespedes, 2001). Using a fitted vaginal pessary, Chaikin et al. (2000) detected occult SUI in 58% of the women. They also noted that none of the women had urethral obstruction after pessary placement. There are multiple techniques used to reduce prolapse, and these methods are not standardized. This has led to variance in the reported incidence of “occult SUI” (Haessler et al., 2005). Veronikis et al. (1997) compared prolapse reduction with rectal swabs, Gellhorn pessary, and a Grave speculum blade. Because prolapse reduction with rectal swabs revealed a significantly lower mid-urethral closure pressure, these authors concluded that the rectal swabs were superior. **Sensitivity and specificity data are lacking with all of the methods used to reduce POP. Accordingly, no method for prolapse reduction has been proven to be superior.**

Performing a concomitant sling at the time of anterior vaginal wall prolapse repair in women without symptoms of SUI or SUI on prolapse reduction remains controversial. Twiss et al. (2007) recommended a simultaneous anti-incontinence procedure at the time of high-stage POP repair because they contend there is no correlation between the preoperative position of the urethra using any method of cystocele reduction and the ultimate position of the urethra after surgery. Thus they contend that the diagnosis of SUI on prolapse reduction is inconsistent and not reproducible. Consequently, SUI on prolapse reduction could be missed. Other authors argue that potential complications from the placement of a concomitant sling equal the risk of SUI on prolapse reduction, and therefore it should offered as a second-stage procedure in those whose incontinence cannot be demonstrated preoperatively (Ballert et al., 2009). Ballert et al. (2009) evaluated a protocol to assess the concomitant placement of MUS at the time of vaginal prolapse surgery. They performed urodynamic testing on 140 women with POP; if SUI was seen, they recommended concomitant sling with prolapse surgery. If no SUI was seen, they repeated the testing with prolapse reduction using a pessary. Again, if occult SUI was demonstrated, they recommended a sling with prolapse surgery. Using this protocol, they found an equal risk of intervention as a result of obstruction from an MUS (8.5%) and intervention for postoperative SUI in a patient without clinical, urodynamic, or occult SUI who did not undergo concomitant sling (8.3%). Therefore the risk of intervention resulting from sling obstruction was equal to the risk of intervention resulting from SUI when no clinical, urodynamic, or occult SUI was present preoperatively and no MUS was placed. Because the need to intervene for complications resulting from MUS equaled the risk of having to perform a secondary sling procedure, the necessity for a secondary surgery in women without SUI after repair of anterior vaginal wall prolapse is not decreased. The risk of intervention in those with clinical symptoms of SUI, but no urodynamic or SUI on prolapse reduction, was 30%.

It has also been reported that a concomitant suburethral sling may contribute to the long-term success of anterior compartment repairs. Goldberg et al. (2001) demonstrated a 55% reduction in postoperative cystocele recurrence in patients who underwent suburethral sling at the time of prolapse repair. Also, Cross et al. (1997) reported that the support created by the simultaneous placement of a pubovaginal sling in grades 3 and 4 cystoceles was improved.

The Colpopexy And Urinary Reduction Efforts (CARE) trial was the first large, randomized, controlled trial evaluating a simultaneous anti-incontinence procedure with POP repair (Brubaker et al., 2006). The investigators evaluated 322 patients with stage 2 to 4 POP who underwent abdominal sacrocolpopexy (ASC), of whom 157 were randomized to concomitant Burch colposuspension and 165 were randomized to ASC alone. The addition of a Burch colposuspension to ASC decreased postoperative SUI from 44.1% to 23.6% at 3 months postoperatively. In a subsequent study examining 2-year outcomes in the same group of patients, the authors found that 32% of patients who underwent concomitant Burch colposuspension were incontinent versus 45% of patients who underwent abdominal sacrocolpopexy alone (Brubaker et al., 2008). Approximately one-third of the women after Burch still had SUI. The Extended CARE (E-CARE) trial enrolled 213 of the original 322 participants with 181 completing 5 years of follow-up and 121 completing 7 years (Nygaard et al., 2013a,b). By year 7, the estimated probability of SUI in the urethropexy group was 62% and 77% in the non-urethropexy group. The time to treatment failure for SUI was longer in the urethropexy group.

Wei and colleagues for the Pelvic Floor Disorders Network (2012) reported on 337 women enrolled in the Outcomes Following Vaginal Prolapse Repair and Mid-Urethral Sling (OPUS) trial. Women with stage 2 or higher POP without symptoms of SUI underwent randomization for a concomitant MUS or sham at the time of vaginal prolapse surgery. At 12 months, urinary incontinence was present in 27% of sling patients and 43% of sham ($P = 0.002$). Higher rates of adverse events were seen in the sling group (bladder perforation, urinary tract infection, bleeding, incomplete bladder emptying; $P \leq 0.05$ for all). There was no difference noted between groups in patient-reported pelvic floor symptoms (Wei et al., 2012).

In summary, there is no standardization of testing for occult SUI. **However, it is clear that all women with advanced-stage anterior compartment prolapse should be screened for the presence of SUI with the prolapse reduced, and consideration should be given to a concomitant anti-incontinence procedure. All women with preoperative symptoms of SUI, occult SUI, or urodynamically proven SUI are at elevated risk of postoperative SUI and should consider a simultaneous anti-incontinence procedure. The risks and benefits of a prophylactic anti-incontinence procedure on continent women should be reviewed with each patient. It is our view that current literature supports selective use of an anti-incontinence procedure at the time of POP repair.**

Key Points: Anterior Compartment Repair

- Anterior compartment defects can be central, lateral, or combined. A central defect results from midline separation or attenuation of the pubocervical (perivesical) fascia. A lateral defect results when the pubocervical fascia detaches from the ATFP.
- Most anterior compartment defects have concomitant lateral and/or apical defects; isolated anterior colporrhaphy is not recommended when additional defects are present.
- Anterior compartment prolapse repair does not suspend the vaginal apex. Patients with anterior compartment and apical prolapse need concomitant repairs that address each defect.
- Anatomic results after anterior repair are improved by the addition of

biologic and synthetic grafts. However, graft complications may occur. Subjective results appear unchanged with the addition of biologic grafts but are improved with the addition of synthetic grafts. QoL measures, reoperation for prolapse, and dyspareunia rates are unchanged by the addition of synthetic mesh. The risk-benefit ratio of graft use must be thoroughly discussed with the patient.

- Anterior colporrhaphy and paravaginal repairs are ineffective alone in the treatment of SUI.
- All women with advanced-stage anterior compartment prolapse should be screened for occult SUI with prolapse reduction, and the risks and benefits of a concomitant anti-incontinence procedure should be discussed with the patient.

Apical Compartment

Middle compartment defects commonly involve the vaginal apex. The organs involved in defects of the middle compartment include the uterus, bowel, or omentum, and depending on the size, bladder and rectum. **The apex remains the cornerstone of vaginal support, and failure to ensure apical support at the time of prolapse correction will undoubtedly increase the risk of recurrence exponentially. Surgical correction can be approached vaginally, abdominally, and minimally invasively with and without uterine preservation.**

Apical Vaginal Vault Prolapse Repairs via Uterosacral Ligament Suspension

The uterosacral vault suspension preserves the orientation of the vaginal axis in its natural position, thus potentially preventing recurrence of prolapse in other segments (Silva et al., 2006). Several authors have reported that the uterosacral ligaments break at specific points rather than an attenuation of the uterosacral cardinal ligament complex, thus allowing for a more site-specific repair (Barber et al., 2000; Jenkins, 1997; Shull et al., 2000). These findings are in contrast to a histologic assessment of the uterosacral ligaments, which calls into question the integrity of this structure for long-term apical support (Cole et al., 2006).

Surgical Anatomy of the Uterosacral Ligaments.

The ligament is attached broadly to S1-S3, variably to S4 (Buller et al., 2001; see Figs. 124.9 and 124.10**)**. It proceeds in a fanlike manner anterolaterally to the cervical os and also onto the proximal portion of the posterior vagina. The ligament can be divided into three portions: the sacral, intermediate, and cervical portions. Beneath the sacral portion of the ligament runs the superior gluteal vein. Although there is great variability in the location of the ureter relative to the ischial spine (Karram et al., 2001), the ureter has been reported to be near the anterior margin of the uterosacral ligament near the cervix. As the ureter courses distally, the distance between the uterosacral ligament and ureter decreases from 4 cm near the sacrum to 0.9 cm near the cervix (Buller et al., 2001). Because of the fibrous tissues of the ureteral sheath, the ureter is subject to kinking from traction caused by sutures placed in the adjacent tissue (Dwyer and Fatton, 2008). If sutures are placed close to the sacrum, there is a risk of entrapping fibers of the sacral plexus trunk of S1-S4 (Siddique et al., 2006; Wieslander et al., 2007). This can result in buttock pain, which radiates to the posterior thigh and popliteal fossa. In a cadaveric study of uterosacral anatomy, Maldonado et al. (2017) concluded that the ischial spine is the most useful pelvic landmark and that increased S3 nerve injury may result from suture placement beyond the mean distance of 4.6 cm from the ischial spine in the direction of the path of the uterosacral ligament cephalad toward the sacrum. **Placing sutures in the intermediate portion of the uterosacral ligament appears to be the optimal site because there are fewer structures to be potentially affected and it provides a stable point of fixation. There is decreased chance of traction affecting the ureter at this point, because it is further away from the ureter and its sheath. Placing the sutures from lateral to medial will also minimize accidentally catching either the ureter or its attachments in the stitch** (Shull et al., 2000). The intermediate segment can be located 1 cm posterior along the palpable uterosacral ligament at the level of the ischial spine with the uterosacral ligament placed on tension (Buller et al., 2001). An advantage of suspension to the uterosacral ligament is that it minimizes injury to the pudendal and gluteal vessels relative to SSL fixation (Barber et al., 2000).

High Uterosacral Vaginal Vault Suspension Technique.

This procedure starts intraperitoneally (Karram et al., 2001). After hysterectomy, the apex is identified on the vaginal cuff at the 3 and 9 o'clock positions, which represent the attachments of the cardinal and uterosacral ligaments (Shull et al., 1993). It is useful to place stay sutures at these dimples before incision. The vaginal epithelium is dissected away from the peritoneum of the hernia sac. Once the dissection has mobilized the hernia sac from the epithelium to the neck of the sac, it is entered, and the sac excised (Fig. 124.11). Laparotomy pads are placed to pack the bowel away. Ischial spines can then be palpated transperitoneally. The uterosacral ligaments will be located posteriorly and medially to the ischial spines. By placement of traction to the stay sutures or by placement of an Allis clamp at the 5 o'clock and 7 o'clock positions of the apex, the uterosacral ligament will tent, and two to four nonabsorbable sutures can be placed through the uterosacral cardinal ligament complex (Fig. 124.12). The ureters should be located lateral to the uterosacral ligaments; however, depending on the degree of the prolapse, there can be significant variability in their location relative to the edge of the uterosacral ligament (Silva et al., 2006). If there is any question regarding their location, temporary catheters may be placed to facilitate their palpation. In placing the needles through the uterosacral ligaments, surgeons must pass them lateral to medial exiting away from the ureter to avoid inadvertent inclusion (Shull et al., 2000). To ensure the proper depth, the suture should be passed at the level of the ischial spines. Subsequent sutures are placed proximal to the last. If an anterior colporrhaphy or sling is planned, it may be done at this point. Suspensory sutures in the uterosacral ligaments are then placed in the most apical portions of the pubocervical and rectovaginal fascia. The highest sutures are then sewn to the most medial portions of the pubocervical and rectovaginal fascia. The more distal sutures are placed most laterally in the pubocervical and rectovaginal fascia and passed out of the vaginal epithelium on each side (Fig. 124.13). Cystoscopy is an essential step after this procedure to confirm ureteral patency and should be performed before trimming the suture because this will facilitate identification of the sutures if they must be removed because of obstruction. If no efflux of urine is seen, the sutures should be removed starting with the most lateral suture of the ipsilateral side. In addition, it is important to perform the cystoscopy after the suture is under tension or tied, not just placed (Yazdany and Bhatia, 2008). As the surgeon ties these suspending sutures, the rectovaginal fascia and pubocervical fascia are brought together at the uterosacral ligament complex, thus resuspending the apex of the vagina and closing the cul-de-sac (Fig.

124.14).

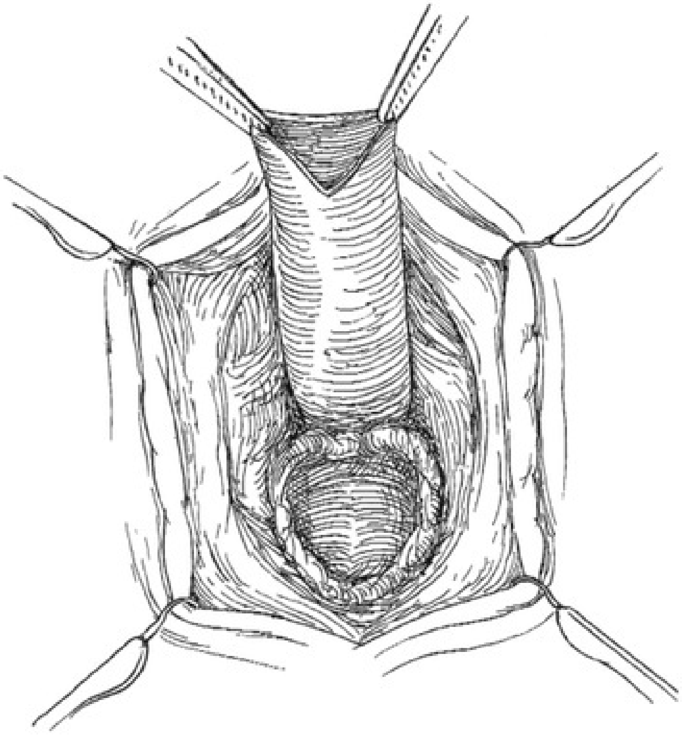

FIG. 124.11 Vaginal enterocele repair. Enterocele sac is identified and opened to reduce its contents. It is then tied in a purse-string suture and the excess is excised. Before the enterocele sac is closed, the peritoneal cavity is entered to access the uterosacral ligament.

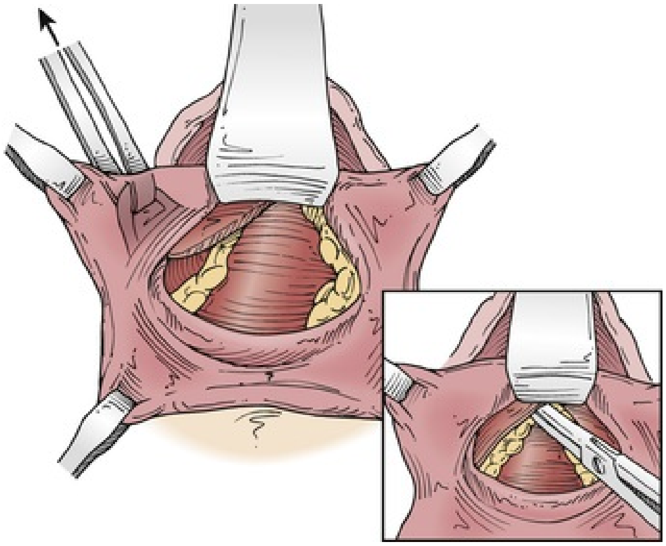

FIG. 124.12 To identify the uterosacral ligament, an Allis clamp is placed on the vaginal epithelium at the right apex and pulled straight upward. With the right uterosacral ligament on tension, the uterosacral ligament is visible in the pelvis. *Inset,* A long Allis clamp is used to grasp the right uterosacral ligament. (Modified from Walters MD, Muir TW: Surgical treatment of vaginal apex prolapse: transvaginal approaches. In Vasavada S, Appell R, Sans P, Raz S, editors: *Female urology, urogynecology and voiding dysfunction*, New York, 2005, Marcel Dekker, pp 663–676.)

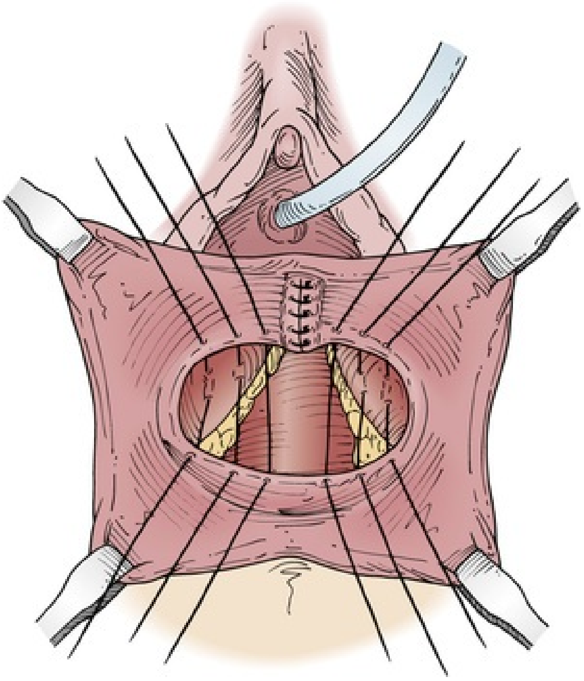

FIG. 124.13 High uterosacral ligament vaginal vault suspension. Three sutures are placed from lateral to medial in each uterosacral ligament. The sutures are brought through the vaginal muscularis anteriorly (pubocervical fascia) and posteriorly (rectovaginal fascia).

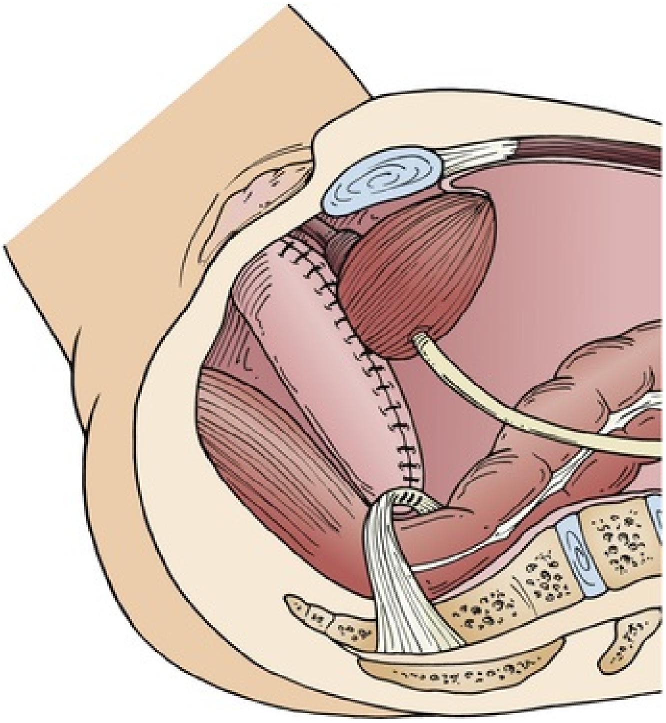

FIG. 124.14 Completed uterosacral vaginal vault suspension with anterior colporrhaphy. (Modified from Walters MD, Muir TW: Surgical treatment of vaginal apex prolapse: transvaginal approaches. In Vasavada S, Appell R, Sans P, Raz S, editors: *Female urology, urogynecology and voiding dysfunction*, New York, 2005, Marcel Dekker, pp 663–676.)

An extraperitoneal approach has also been described (Dwyer and Fatton, 2008). A midline incision is made, depending on concomitant prolapse. The vaginal epithelium is then dissected away from the endopelvic fascia, and the enterocele sac is identified and dissected free of the vault. Dissection is continued laterally until the uterosacral cardinal ligament complex is identified posterior and medial to the ischial spine. Palpation to tent the uterosacral cardinal ligament complex is facilitated by placing tension on the vagina. Use of the Briesky-Navratil retractor to retract the bladder and ureters anteriorly has prevented ureteral obstruction through traction or injury (Fatton et al., 2009). Once the ligaments are identified, the sutures are placed in a similar fashion to the intraperitoneal approach. Cystoscopy and vaginal closure are performed as described previously.

Abdominal Approach to the Uterosacral Ligaments.

The uterosacral ligaments may be accessed transabdominally (Lowenstein et al., 2009). This technique begins by elevating the uterus at the time of abdominal hysterectomy. Three permanent sutures are placed in each of the uterosacral ligaments proximal and medial to the ischial spine. They are numbered in the manner described by Shull et al. (2000) (Fig. 124.15). Once the hysterectomy has been performed and the cuff has been closed, the sutures are placed sequentially through the anterior and posterior leaves of the endopelvic fascia. By reapproximating the anterior and posterior muscularis of the vagina, any potential enterocele defects are closed and the cuff is elevated toward the sacrum recreating the normal vaginal axis. Cystoscopy is performed after tying the sutures, which are left uncut until efflux of urine is demonstrated. If no urine is seen, the most lateral ipsilateral suture is removed, and subsequent sutures are taken down in sequence.

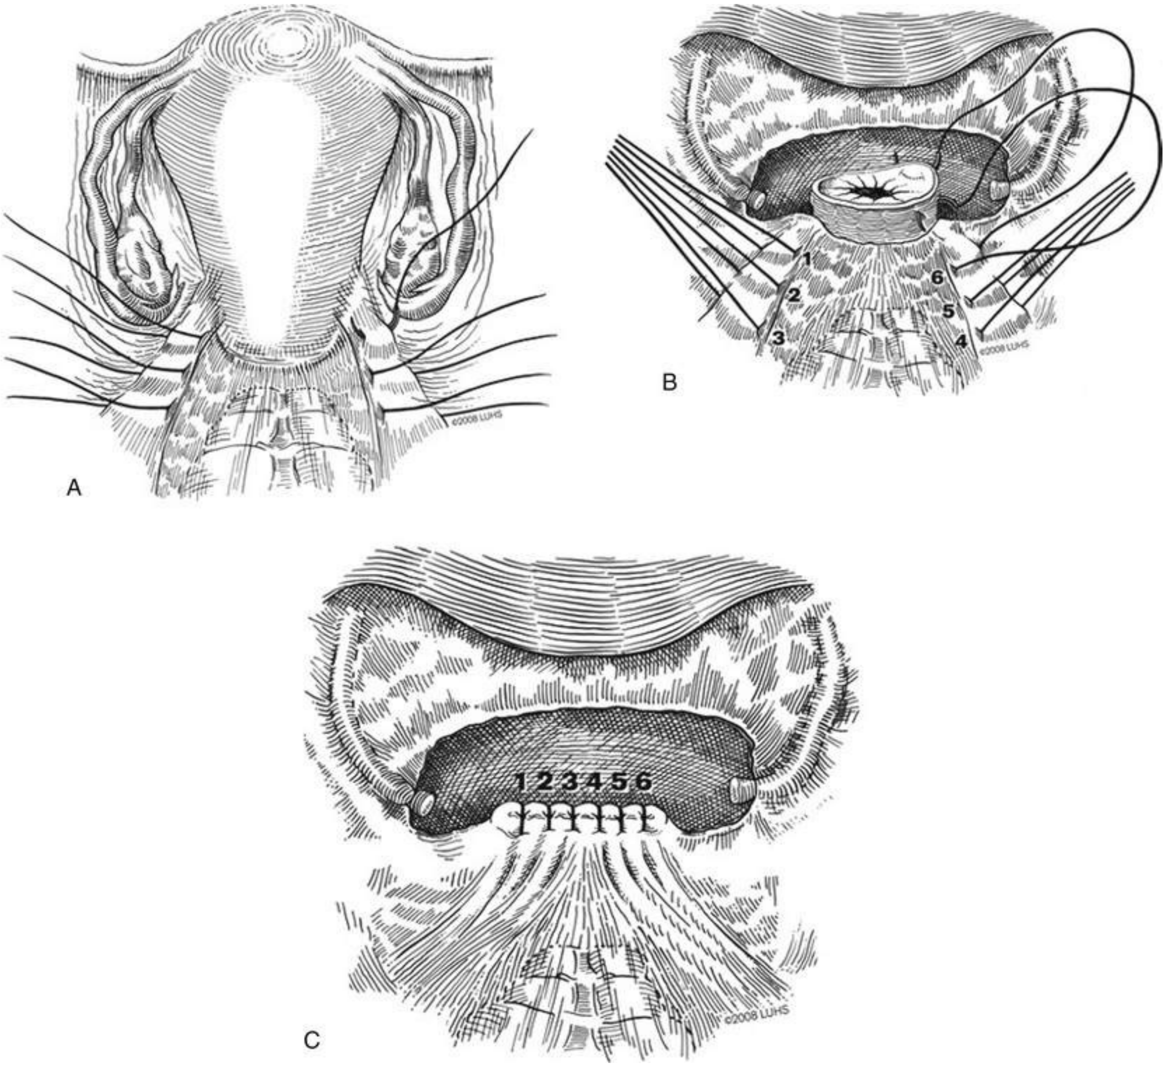

FIG. 124.15 (A) Three permanent sutures are placed in each of the uterosacral ligaments medial to the ischial spine. (B) One end of each of the 6 sutures is placed serially across vaginal apex through the anterior

endopelvic fascia and the other end through the posterior endopelvic fascia. (C) All sutures are tied to reapproximate the anterior and posterior vaginal muscularis, to close any potential enterocele defect, and to elevate the vaginal apex toward the sacrum. Uterosacral Ligaments Results.

Transvaginal uterosacral ligament suspension has been evaluated primarily through uncontrolled retrospective case series. Table 124.5 summarizes the available literature with a mean objective success of 85% and a range of 48% to 96%. Mean reoperation rate for prolapse from the data in Table 124.5 is 5.8%. In 2010 Margulies et al. performed a meta-analysis and documented success based on POP-Q stage in the anterior (81.2%), apical (98.3%), and posterior (87.4%) compartments. Less than half the studies in the pooled analysis reported postoperative prolapse symptoms. In those that did, 82% to 100% of patients reported relief. Ureteral kinking or injury was reported in 1% to 11% of cases. Shull et al. (2000) have the largest reported series of patients who underwent uterosacral ligament suspension. Of 289 patients who followed up, a majority (87%) had no recurrence of support defect at any site on any postoperative examination. Only 5% of the patients had grade 2 prolapse or greater. The most common site was the anterior compartment in which 10 patients had grade 2 or 3 defects. One patient required ureteroneocystostomy. Two patients required removal of suspensory sutures. Karram et al. (2001) reported on 168 patients who underwent uterosacral vaginal vault suspension. Eighty-nine percent reported satisfaction with the results of the procedure. Ten women (5.5%) underwent subsequent surgery for recurrent prolapse. Seven women experienced a major intraoperative complication, 5 (2.4%) ureteral injuries, 1 small bowel injury, and 1 pelvic abscess requiring diverting colostomy (Karram et al., 2001). Silva et al. (2006) evaluated long-term (5.1 years) anatomic and functional outcomes of high uterosacral vaginal vault suspension. Surgical failure in one or more compartments occurred in 11 patients (15.3%); apical recurrence occurred in 2 of 78 patients. Seven patients had de novo postoperative dyspareunia. Patient-reported outcomes indicated improvement in irritative voiding, obstructive voiding, stress incontinence, and overall urinary symptoms compared with preoperative scores.

A randomized control trial sponsored by the Pelvic Floor Disorders Network, the OPTIMAL trial, compared uterosacral ligament suspension to sacrospinous ligament fixation in 354 patients (Barber et al., 2014). After 2 years the surgical success rate was 64.5%, and perioperative pelvic floor muscle training was not associated with an improved outcome. In contrast, in a single institution study Lavelle et al. (2018) reported a failure rate of 25.7% in patients after uterosacral suspension in patients with stage 3 POP, which was higher than a cohort of patients undergoing ASC (7.8%).

Fatton et al. (2009) examined their results performing an extraperitoneal bilateral uterosacral vaginal vault suspension (n = 110) with a mean follow-up of 2 years. Concurrent procedures included anterior colporrhaphy (20%), anterior mesh reinforcement (49%), posteriorly colporrhaphy (56%), and sling (29%). Recurrence at the apex was noted in 4.6% of patients. Global anatomic success was reported in 85.5%. Mesh exposure occurred in 19.3%, was diagnosed within 6 months in the majority of the patients, and required conservative or minor interventions. The authors conclude that this procedure is effective at restoring apical support while avoiding the morbidity of an intraperitoneal operation.

Sacrospinous Ligament Fixation

The sacrospinous ligament fixation was first described by Richter in 1942 but was not widely used until Nichols (1982) reported on the technique. The sacrospinous ligament fixation has been shown to be an effective method to correct apical prolapse (Cruikshank and Muniz, 2003). This technique is appealing because of its extraperitoneal approach and consistency as a strong structure on which to anchor the apex. Access to the spine was originally achieved from the posterior approach, although dissection from the anterior approach may also be performed via the paravaginal space (Cespedes, 2000;

Winkler et al., 2000). The advantages of sacrospinous ligament suspension are the ability to repair concomitant pelvic floor defects, absence of a laparotomy (Morley and DeLancey 1988), shorter hospital stay (Brown et al., 1989), preservation of vaginal length and function (Brown et al., 1989; Morley and DeLancey, 1988), and cost effectiveness (Brown et al., 1989). The structures at risk with this technique include the pudendal or inferior gluteal vessels and the sciatic or pudendal nerves. Pudendal nerve entrapment results in posterior buttocks pain, which may radiate down the back of the thigh. **A disadvantage of this approach is the alteration in vaginal axis, which results in apical displacement posteriorly and to the right side when unilateral fixation is used. This posterior displacement can result in anterior compartment recurrence, even when an anterior repair is performed** (Morley and DeLancey, 1988; Sauer and Klutke, 1995; Shull et al., 1992). **In younger, more active women, contemporary data suggest favoring abdominal repairs.**

Sacrospinous fixation may be performed unilaterally or bilaterally (Pohl and Frattarelli, 1997). With the unilateral suspension, right-sided placement is generally preferred. Technically, it is easier to place the sutures on the right ligament for a right-handed surgeon (Sauer and Klutke, 1995). Cespedes reported success using the bilateral anterior support and noted the advantage of more midline location of the vaginal apex (Cespedes, 2000). Although bilateral placement has been advocated (Nichols, 1982), there is little to support the advantage of bilateral fixation over unilateral fixation when examining outcomes (Morley and DeLancey, 1988).

Surgical Anatomy of the Sacrospinous Ligament Fixation.

The sacrospinous ligament is approximately 7 to 8 cm in length (Morley and DeLancey, 1988) and extends from the ischial spine laterally, coursing medially under the coccygeus muscle and inserts into the sacrum. The pudendal nerves and vessels are close to the ligament, just proximal to their course around the ischial spine (Fig. 124.16). In addition, the hypogastric plexus of veins are located superiorly, and the hemorrhoidal vessels are located medially to the sacrospinous ligament (Morley and DeLancey, 1988), thus retraction should be carried out carefully in these respective areas. To avoid the gluteal vessels, the suture should be placed into the ligament and not behind it (Kettel and Hebertson, 1989). Pudendal nerve entrapment may result in pain, which localizes to the buttocks or perineum. This may be avoided by placing sutures medial to the ischial spine, about 1.5 cm (Alevizon and Finan, 1996; Sauer and

Klutke, 1995). Branches from the S3 and S4 nerve roots are more likely to cause postoperative gluteal pain. Precise suture placement on the ligament, limiting the depth of needle penetration into the ligament, and avoiding needle entry or exit above the upper extent of the sacrospinous ligament may avoid nerve entrapment and postoperative gluteal pain (Florian-Rodriguez et al., 2016).

FIG. 124.16 Anatomy of the sacrospinous ligament and surrounding structures. Note the close proximity of the pudendal vessels, hypogastric plexus, inferior gluteal vessels, and sciatic nerve. (From Walters M, Karram M: *Urogynecology and reconstructive pelvic surgery,* ed 3, Philadelphia, 2006, Mosby.)

Katrikh et al. (2017) also found that the middle segment of the sacrospinous ligament has the lowest incidence of nerves and arteries associated with it and that the nerves supplying the pelvic floor muscles are at a higher risk of entrapment than the pudendal nerve. **Thus the optimal position of the suture placement is 1.5 to 3.0 cm medial to the ischial spine, directly into the SSL.** Placing it too far medially may risk failure of the repair as the sacrospinous ligament fans and thins as it inserts into the sacrum (Sauer and Klutke, 1995). In addition, there is a higher concentration of sacral nerves in this medial location. Barksdale performed a cadaveric study to assess the histology of the sacrospinous ligament, taking segments near the ischial spine, middle and sacral portions of the ligament (Barksdale et al., 1997). The highest concentration of nerves was found in the sacral portion of the SSL and the lowest near the ischial spine. Although it was postulated that the nerves embedded in the SSL were a potential source of neuropathic pain, no clinical correlation could be made in this cadaveric study. Lantzsch et al. (2001) concluded that localization and depth of the suture can also influence the occurrence and intensity of sciatic neuralgia.

Sacrospinous Ligament Fixation Technique.

The procedure starts by marking the apex of the vagina. The vaginal apex is then reduced to the sacrospinous ligament(s) intended to be used. This site of attachment is then tagged (or marked) for later fixation. Depending upon concomitant compartmental defects, the SSL can be approached either anteriorly or posteriorly. A standard midline vaginal incision is made in the vaginal epithelium, which is separated from the rectovaginal septum posteriorly or pubocervical fascia anteriorly. If an anterior compartment repair will be performed, the SSL may be approached anteriorly, exposing the paravesical space. The tissue attachments overlying the spine and ligament are swept medially. Alternatively, if the posterior approach is used, the surgeon must enter the perirectal space by bluntly mobilizing the rectum medially. Upon entering the perirectal space, the ischial spine is identified. With further dorsal and medial blunt dissection, the SSL is palpated. Blunt dissection is continued to ensure that the rectum is retracted medially and the ligament is adequately exposed. At this point Heaney or Breisky-Navratil retractors are very useful to visualize the ligament and facilitate suture placement. In addition, lighted retractors can provide added visualization. The sacrospinous ligament is then palpated. The suture is placed approximately one to two fingerbreadths medial from the spine to avoid damage to the structures in Alcock canal.

Several different methods have been used to fix the suture to the sacral spinous ligament. The Capio Suture Capturing Device or the Capio Slim Suturing Device (Boston Scientific, Marlborough, MA) enables the suture to be placed by palpation. Alternatively, the Miya Hook (CooperSurgical, Trumbull, CT) (Miyazaki, 1987), the Autosuture Endo Stitch Suturing Device (Covidien, Norwalk, CT) (Schlesinger, 1997), Deschamps Ligature Carrier, or freehand needle driver passage may be used to place the sutures under direct vision. Two sutures are most commonly placed. In cases of bilateral SSL fixation, one suture may be placed on each ligament. In the case of unilateral SSL fixation, the placement of the sutures on the ligament 2 cm apart will prevent constriction of the vaginal apex. Additional repairs may be performed at this point. After this, the previously placed SSL sutures are brought out of the vagina to the previously marked vaginal apex (Fig. 124.17). If a permanent suture is used for sacrospinous ligament fixation (SSLF), a pulley stitch is used, which ensures that the knot of the suture will remain internal, if needed. To create a pulley stitch, tying a knot onto the fibromuscular portion on the visceral side of the vagina creates a fixed point. The free end of the suture is then pulled, thus suspending the apex to the SSL, and this is then secured by tying a secure knot. Importantly, this resultant knot remains internal and is not within the vaginal canal. Closure of the vaginal wall halfway, before tying down the sutures, is useful, because the suspended apex may be difficult to reach. The sutures should be tied so that the vaginal apex is firmly attached to the coccygeal sacrospinous ligament complex with no intervening suture material bridging a gap (Morley and DeLancey, 1988; Sze and Karram, 1997). Palpation of the suture behind the vaginal cuff will ensure that the suture is tied securely. It is useful to leave the secured suture untrimmed until the cystoscopy is performed in case the suture must be removed. Once efflux is visualized bilaterally, the anchoring suture is trimmed, and the remainder of the vaginal incision is closed.

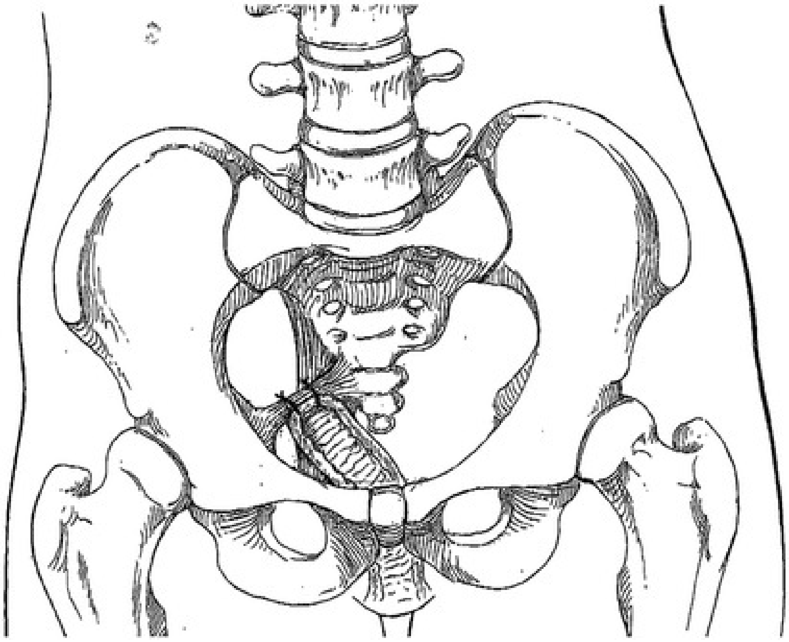

FIG. 124.17 Sacrospinous ligament fixation. With a unilateral suspension, the vagina is deflected to the right side and caudally. (From Richter K, Albright W: Long-term results following fixation of the vagina on the sacrospinous ligament by the vaginal route. *Am J Obstet Gynecol* 141:811–816, 1981.)

Sacrospinous Ligament Fixation Results (Table 124.6).

Early data reported the feasibility and success associated with this approach to apical correction. Nichols reported outcomes of SSLF in 163 patients, some with "massive" vaginal eversion and procidentia. There were no reported recurrences of vaginal vault prolapse; however, nine patients reported that the vagina was "too narrow" postoperatively (Nichols, 1982). This outcome was also observed in a study by Richter and Albrich (1981), who reported excellent patient satisfaction, although 8 patients were reluctant to resume sexual relations because of a perception of vaginal narrowing. Morley and DeLancey (1988) reported on 100 patients who underwent SSL fixation, 33 of whom underwent isolated apical treatment, while 67 had concomitant prolapse repairs. Apical success was noted in 95.7%, 90.1% globally; 4 patients had prolapse in the anterior compartment. They noted that the long-term results were acceptable with minimal adverse effects.

[a]Prospective and retrospective cohorts with n >50 published since 1985 and SSLS arms of 3 RCTs comparing SSLS with abdominal sacrocolpopexy (ASC).

Bilateral SSL suspension was compared with abdominal sacrocolpopexy in a prospective randomized study (Benson et al., 1996). Time to failure was shorter in the SSL group compared with the abdominal group (11 vs. 22 months); the vaginal group had 12 cystoceles requiring reoperation versus 4 cystoceles in the abdominal group. Sauer and Klutke (1995) reported on 24 patients with a mean follow-up of 13.8 months. Blood loss was minimal, and no transfusions were needed, but mild postoperative buttock pain was noted that resolved by 3 months. In 21 of 24 patients there was no recurrence of prolapse at the apex, but one patient underwent repeat operation for a significant cystocele. Meschia et al. (1999) reported on 103 patients who underwent SSL fixation and found excellent results for the posterior and apical compartments but disappointing results for the anterior compartment: 16% had grade II or greater prolapse. In a systemic review of published papers from 1995 to 2011, 24 studies reported an overall cure rate of 84.6% after SSLF. The apical recurrence rate was 5.3%, and the anterior recurrence rate was 18.3% (Tseng et al., 2013).

The anterior compartment has been reported as a particularly vulnerable site for developing a defect after sacrospinous vaginal vault suspension. Recurrent cystoceles have been reported in 7.6% to 92% of patients postoperatively (Morley and DeLancey, 1988; Pasley, 1995; Richter and Albrich, 1981). This has been attributed to vaginal retroversion (posterior displacement). This is noted not only postoperatively but also intraoperatively, although many who develop anterior defects remain asymptomatic and do not undergo subsequent surgery to correct the anterior compartment defect (Paraiso et al., 1996). The Pelvic Floor Network Dyfunction Network evaluated anatomic anterior compartment prolapse recurrence and the effect of concomitant repair after vaginal apical procedures. Patients with higher stages of POP (Ba > +1) undergoing SSLF and concomitant anterior compartment repair did have improved overall success rate. In patients with lower stage POP, undergoing uterosacral ligament suspension, a concomitant anterior repair did not improve postoperative anatomic success rates (Nager et al., 2019).

Several authors have demonstrated the feasibility and efficacy of an anterior approach to the SSL vaginal vault suspension (Cespedes, 2000; Winkler et al., 2000). Winkler et al. (2000) reported that the anterior compartment recurrence rate after an anterior SSL fixation and anterior repair was 9%, in contrast to a 24% after SSL fixation with posterior repair. Cespedes reported on the bilateral anterior approach and noted no recurrences. Some of the theoretic advantages of the anterior approach include improved ability of the vagina to withstand increased intraabdominal pressures (Pohl and Frattarelli, 1997), and less likelihood of rectal injury (Sauer and Klutke, 1995). Again, a low incidence of anterior compartment recurrence was noted at 7% (Cespedes, 2000).

Successful healing in the short term may predict long-term success of the SSL suspension. Shull et al. (1992) reported on 81 women undergoing sacrospinous ligament suspension; 72% had previous pelvic surgery. Those who showed absence of any compartment defect at the 6-week follow-up had only a 3% likelihood of requiring additional reconstructive surgery within 2 to 5 years.

Sacrospinous Ligament Fixation Complications.

Cruikshank and Muniz (2003) reported 15% of patients experiencing gluteal pain after SSL fixation on the ipsilateral side. Generally, this pain has shown spontaneous resolution within 2 to 3 months when delayed absorbable sutures were used (Maher et al., 2001). Postoperative mild to moderate neuropathic pain can be managed with observation, and patients should be counseled that duration may be as long as 3 months (Sauer and Klutke, 1995). Injection of the nerve with local anesthetic has been used for treatment (Lantzsch et al., 2001). In patients with severe or persistent radicular neuropathic type pain, suture removal may be considered. Rectal perforation has also been reported with this procedure. When a perforation was recognized at the time of surgery and repaired primarily, no sequelae were observed (Richter and Albrich, 1981; Sauer and Klutke, 1995). In addition, injury to the pudendal nerve and internal pudendal vessels may occur with sutures placed too near the ischial spine.

Iliococcygeus Suspension

The iliococcygeus suspension has the advantage of maintaining the vagina in a more normal axis and is useful in cases in which the uterosacral ligaments are insufficient for attachment or cannot be identified. With this technique, the vaginal vault is attached to the fascia of the iliococcygeus muscle as the anchoring site in contrast to the uterosacral or sacrospinous ligaments.

Iliococcygeus Suspension Technique and Results.

The approach is similar to the uterosacral and SSLF and is usually approached extraperitoneally. The fascia of the iliococcygeus muscle is identified lateral to the rectum and distal the ischial spine (Shull et al., 1993). The point of suture fixation is placed 1 cm distal to the ischial spine, near the insertion of the ATFP. This suture is then passed through the condensation of connective tissue at the apex of the vagina anteriorly through the pubocervical fascia and posteriorly through the rectovaginal fascia (Fig. 124.18). Another suture is placed on the contralateral side in a similar manner. It is recommended that bilateral suture fixation be performed to achieve optimal results. Once the sutures are tied securely, the vagina will be suspended bilaterally. As in SSLF, the sutures may be placed through an anterior or posterior approach. Special needle drivers and lighted retraction are useful to facilitate suture placement. In cases using permanent suture a pulley-stitch technique is applied, tying the knot internally.

Shull et al. (1993) reported on bilateral attachment of the vaginal cuff to the iliococcygeus fascia in 42 patients. Eight patients experienced pelvic support loss postoperatively, 3 in the middle (apical) compartment, 2 in the posterior compartment, and 4 in the anterior compartment. Six patients required additional surgery. Meeks et al. (1994) reported an anatomic cure of 96% in 110 patients. Intraoperative complications included rectal and bladder laceration and hemorrhage requiring transfusion. Postoperative complications included vaginal cuff abscess, fever, and transient femoral neuropathy. Maher et al. (2001) reported a 53% cure rate in 50 patients, and 19% of the patients experienced buttock pain. After a median follow-up of 66.8 months, Serati et al. (2015) reported overall cure rates of 84.1% in a single-institution study of 44 patients. Only preoperative stage 4 POP independently predicted prolapse recurrence (Serati et al., 2015).

Abdominal Sacrocolpopexy

Abdominal sacrocolpopexy should be considered a treatment option in the following clinical scenarios: failed previous vaginal repair, isolated uterine prolapse and/or enterocele, younger women, women with a highly active lifestyle, women who are sexually active, and women who desire one of the consistently most durable repairs at the expense of a potentially more invasive approach. In these patients, **ASC is an excellent choice because it maximizes functional vaginal length without significant distortion of the anatomic vaginal axis.** As discussed earlier, other pelvic floor defects and stress urinary incontinence can be addressed at the same time. In addition to open surgery, robotic-assisted laparoscopic and pure laparoscopic approaches have been described and are commonly used today (Daneshgari et al., 2006; Elliott et al., 2006; Rozet et al., 2005; Sundaram et al., 2004). The principles of the operation remain the same regardless of the approach.

Open Abdominal Sacrocolpopexy Technique.

The critical elements of the operation include the use of permanent mesh (polypropylene) or autologous fascia as graft material and secure fixation of the graft to the sacral promontory and vaginal cuff.

The patient is positioned in the low lithotomy position, providing transvaginal and transabdominal access. A Pfannenstiel or low midline abdominal incision may be used. Upon surgical entry into the peritoneal cavity, it is important to achieve exposure of true pelvis by careful packing of the small intestine and sigmoid colon. This is accomplished by releasing all adhesions in the pelvis and packing the bowel above the level of the sacral promontory and displacing the sigmoid to the left, exposing the sacral promontory and posterior peritoneum. An incision is made in the posterior peritoneum over the sacral promontory, extending inferiorly along the right lateral aspect of the rectum towards the cul-de-sac. Electrocautery is used when dividing the fatty tissue over the promontory to minimize bleeding and improve visualization. Careful dissection in this area is essential to avoid shearing of presacral veins because severe bleeding may occur. The middle sacral vessel traverses over the promontory and should be avoided. As the fatty tissue is dissected free, the anterior surface of the sacral promontory is visualized, usually by identification of the anterior longitudinal ligament. Two to three interrupted, nonabsorbable monofilament sutures are placed in the anterior longitudinal ligament with care to avoid perforation of the midline sacral vessels. Generally, sutures are placed under the vessels and tied down over the top of the vessels. Alternatively, if vessels overlie the ligament, bipolar energy can be used on the vessels to prevent bleeding before placing the sutures. These sutures are safely tagged for later placement into the mesh graft (Fig. 124.19). Alternatively, commercially available tacking devices may be used for securing the graft to the sacral promontory, although minimal data exist to confirm comparable efficacy.

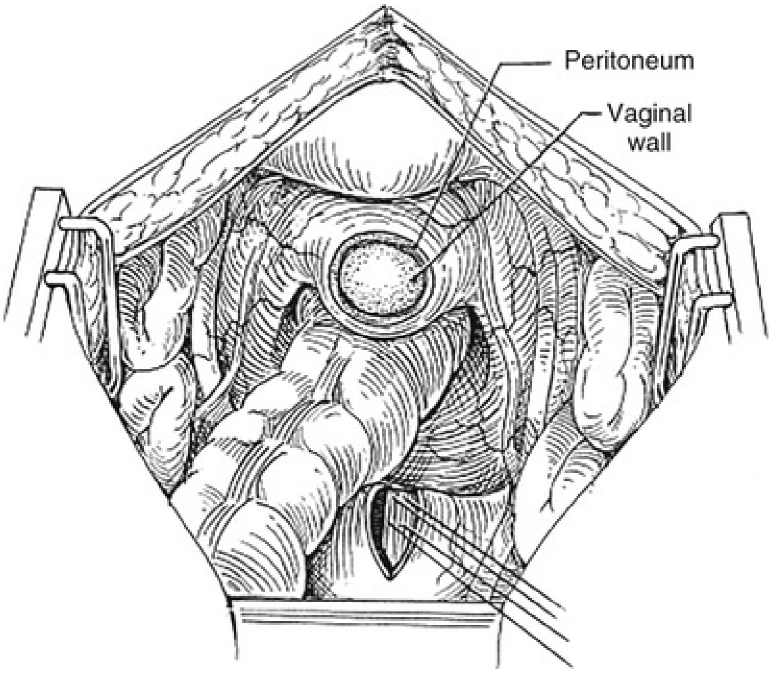

FIG. 124.19 Abdominal sacrocolpopexy. (A) Incision in the peritoneal cuff overlying the vagina, exposing the vaginal cuff. (B) Two permanent sutures are placed in the sacral promontory to secure the graft material. (C) Long incision in the posterior peritoneum, which will be used to cover the graft material. (From Winters JC, Cespedes RD, Vanlangendonck R: Abdominal sacral colpopexy and abdominal enterocele repair on the management of vaginal vault prolapse. *Urology* 56[6 Suppl 1]:55–63, 2000.)

After placing an end-to-end anastomosis sizer or commercially available vaginal stent in the vagina, the surgeon identifies the enterocele sac, if present, and secures it with an Allis clamp. If the enterocele is large, a Halban culdoplasty can be performed by placing linear permanent or delayed absorbable sutures through the posterior peritoneum and on the outer surface of rectum up to the vaginal cuff (Geomini et al., 2001). Upward retraction of the sizer assists in exposing the cul-de-sac. Usually 4 to 6 sutures are used to complete adequate cul-de-sac closure. This technique of (Fig. 124.20) closure is in contrast to the Moschowitz procedure, which involves purse-string closure and may predispose to ureteral angulation and obstruction. Alternatively, if an aggressive posterior vaginal dissection to the perineum is to be performed (see later) for placement of an extended piece of posterior mesh with subsequent retroperitonealization of the mesh, the culdoplasty is usually not needed.

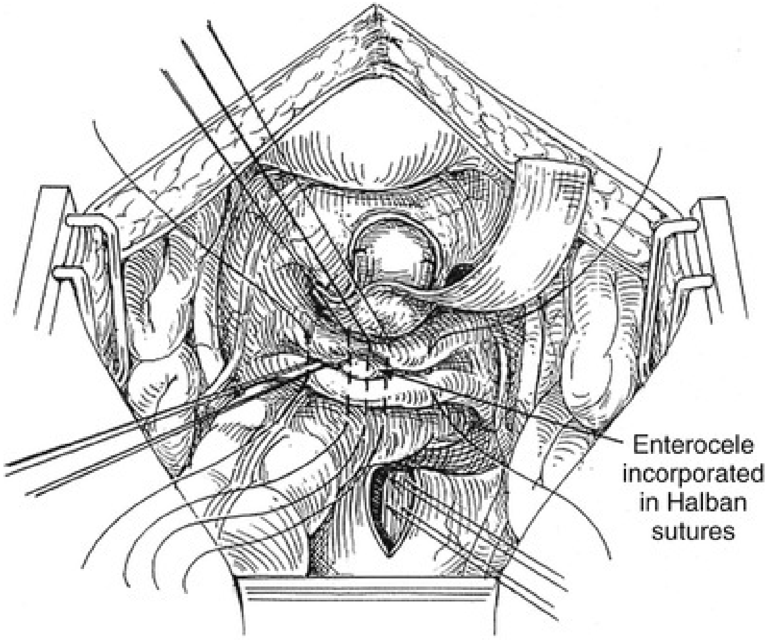

FIG. 124.20 Abdominal sacrocolpopexy Synthetic graft material is sutured securely to vaginal cuff using multiple interrupted permanent sutures. The peritoneal cul-de-sac is closed using linearly placed sutures to obliterate this potential space. (From Winters J, Cespedes R, Vanlangendonck R: Abdominal sacrocolpopexy and abdominal enterocele repair in the treatment of vaginal vault prolapse. *Urology* 56[6 Suppl 1]:55–63, 2000.)

The peritoneum over the vaginal cuff is incised, and the peritoneum is dissected off the anterior vaginal wall (see Fig. 124.20). There is significant variability in the amount of vaginal dissection reported. Some pelvic surgeons perform minimal dissection of the peritoneum and bladder off the vagina, enough to fix the mesh for 4 to 5 cm on each side, whereas other techniques describe a more extensive dissection that involves lifting the posterior bladder wall and trigone off the underlying vagina, as well as dissecting all the way to the perineal body. With the advent of robotic techniques, it seems that more extensive dissections are being carried out with longer mesh segments attached to the bladder, although there are no controlled studies to identify the optimal technique of graft placement to the vagina. Several mesh options exist for ASC, including prefabricated Y-shaped soft polypropylene mesh and sheets of soft polypropylene mesh that can be cut and fashioned to the surgeon's preference. A polypropylene, macroporous, monofilament, nonabsorbable mesh is recommended. A roughly 4.0-cm wide by roughly 6.0-cm long anterior segment of mesh is sutured to the exposed anterior vaginal wall using 6 to 8 permanent sutures, although some surgeons are now using delayed absorbable sutures to avoid suture complications (Fig. 124.21). Care is taken to identify the border of the bladder to avoid suturing the graft to the bladder and to secure the lateralmost portions of the mesh to prevent folding. An obturator in the vagina is useful to facilitate suture placement and secure the mesh to the vagina. The graft is secured to the vagina by folding over the cuff of the vagina and allowing the long end of the graft to exit posteriorly and extend to the sacrum. (Alternatively, a T-shaped configuration of the graft may be created. The short arm of the T is placed on the top of the vagina, and the long arm of the T is secured to the lower end of the vagina.) The posterior peritoneum is dissected off the posterior wall of the vagina entering the space between the rectum and vagina. The posterior segment of the mesh is then attached to the posterior vaginal wall with 6 to 8 interrupted monofilament delayed absorbable or nonabsorbable sutures. At this step, the central sutures from the culdoplasty are placed through the long arm of the mesh if desired.

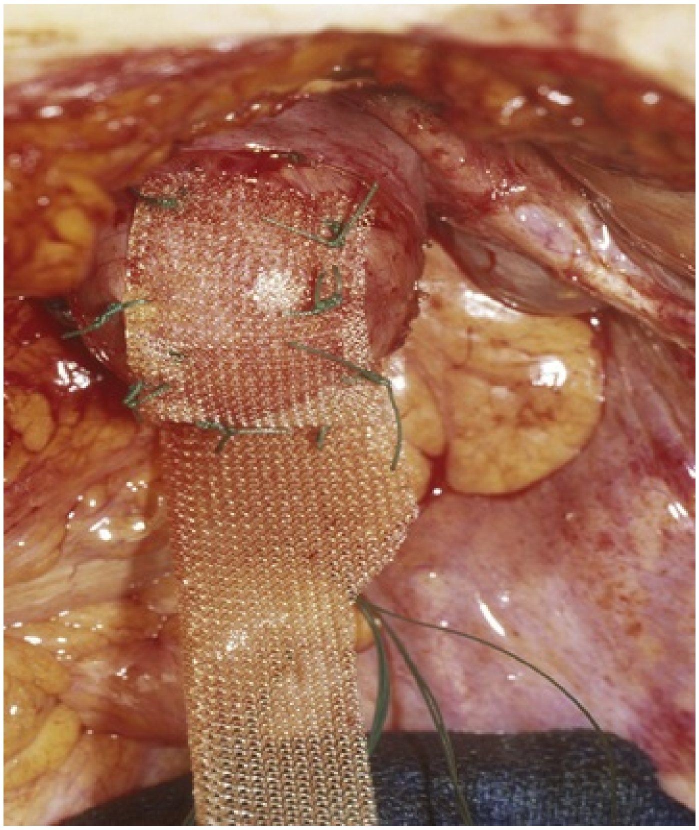

FIG. 124.21 Abdominal sacrocolpopexy: intraoperative view. Permanent mesh material sutured to vaginal cuff. Note: end-to-end anastomotic sizer used to provide exposure of vaginal cuff. (From Scarpero H, Cespedes R, Winters J: Abdominal approach to the repair of vaginal vault prolapse. *Tech Urol* 7:139–145, 2001.)

The graft is then secured to the sacral promontory. Care must be taken to avoid excessive tension. Placing the obturator all the way into the vagina but not pushing the vagina upward establishes the proper length for the graft. The graft is placed along the right lateral aspect of the rectum in the space previously developed by extending the opening of the peritoneum from the sacrum. A space of 2 fingers' width between the graft and the rectum prevents compression of the rectum over the graft (Fig. 124.22). Tensioning in this fashion is not feasible with a robotic or laparoscopic approach. It requires a visual cue of the mesh attachment while extending the vagina cephalad with an end-to-end anastomotic sizer to its maximal length without actively stretching it. The promontory sutures are then brought through the mesh and tied down securely. Any excess mesh is trimmed after fixation to the sacrum. Last, the graft is positioned in the retroperitoneal space by closing the posterior peritoneum over the graft and covering the graft on the vagina with the superior edge of the anterior peritoneum and bladder flap. Stress incontinence procedures (if indicated) are then performed. Cystoscopy is performed to ensure patency of the ureters. The patient is then examined to determine if any ancillary transvaginal prolapse repairs are needed.

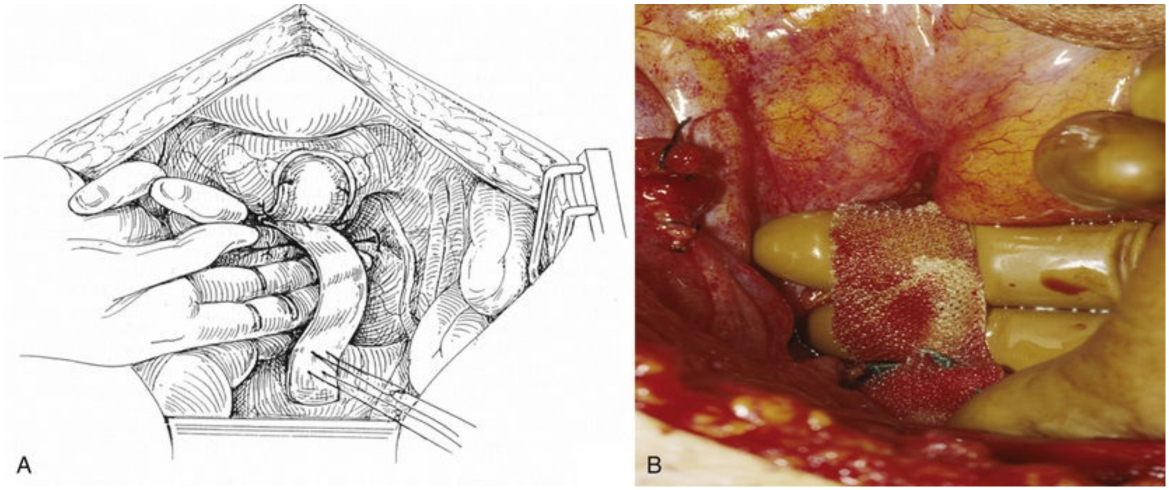

FIG. 124.22 Abdominal sacrocolpopexy. (A) Graft is secured without tension to sacral promontory. (B) Intraoperative view. (A, From Winters J, Cespedes R, Vanlangendonck R: Abdominal sacrocolpopexy and abdominal enterocele repair in the treatment of vaginal vault prolapse. *Urology* 56[6 Suppl 1]:55–63, 2000. B, From Scarpero H, Cespedes R, Winters J: Abdominal approach to the repair of vaginal vault prolapse. *Tech Urol* 7:139–145, 2001.)

Robotic-Assisted Laparoscopic Sacrocolpopexy Technique.

Sacrocolpopexy may be performed with a minimally invasive technique using laparoscopy or robotic surgery. The basic steps of the procedure are the same whether performed abdominally, robotically, or laparoscopically and differ mainly by the method of abdominal entry, trocar placement, docking the robotic patient cart, and method of suture fixation. The da Vinci surgical system (Intuitive Surgical, Sunnyvale, CA) is currently the only widely used robotic surgical system in the United States. The patient can be placed on a Pink Pad (Xodus Medical, New Kensington, PA) or another device to prevent slippage. After administration of general anesthesia, the patient is properly positioned in Allen stirrups in a low lithotomy position, the arms are properly tucked to the side, and all bony prominences are padded.

A pelvic exam is performed, the abdomen and vagina are surgically prepared, a Foley catheter is inserted into the bladder, and nasal/oral gastric tube is placed. Trocar placement begins with entry into the abdominal cavity via the technique with which the surgeon is most experienced. Laparoscopic entry can be performed with an open or closed technique; although the umbilicus is the most frequent site of entry, other sites include the left upper quadrant or subxiphoid and less commonly, transuterine and transvaginal. Closed-entry techniques offer quick access with low risk of injury (Bonjer et al., 1997; Catarci et al., 2001). However, meta-analyses have not shown that any of the techniques are superior to the others (Ahmad et al., 2008; Vilos et al., 2007).

Typically starting at the umbilicus, the surgeon makes an incision at the base of the umbilicus and an 8.5-mm robotic camera trocar is placed, the abdomen is inflated with CO_2 gas, and a diagnostic survey of the abdomen is performed. Two to three additional 8.5-mm robotic trocars are placed at least 9 cm apart in either a semi-lunar or W configuration. An additional 8.5- to 11-mm laparoscopic trocar is placed on the right side of the patient to allow for the surgical assistant access (Fig. 124.23). The bed is moved into the Trendelenburg position, and side or parallel docking is preferred to allow access to the vagina, bladder, and rectum intraoperatively. The typical robotic instruments used are the robotic monopolar scissors, robotic Maryland bipolar instrument, and a robotic bowel grasper.

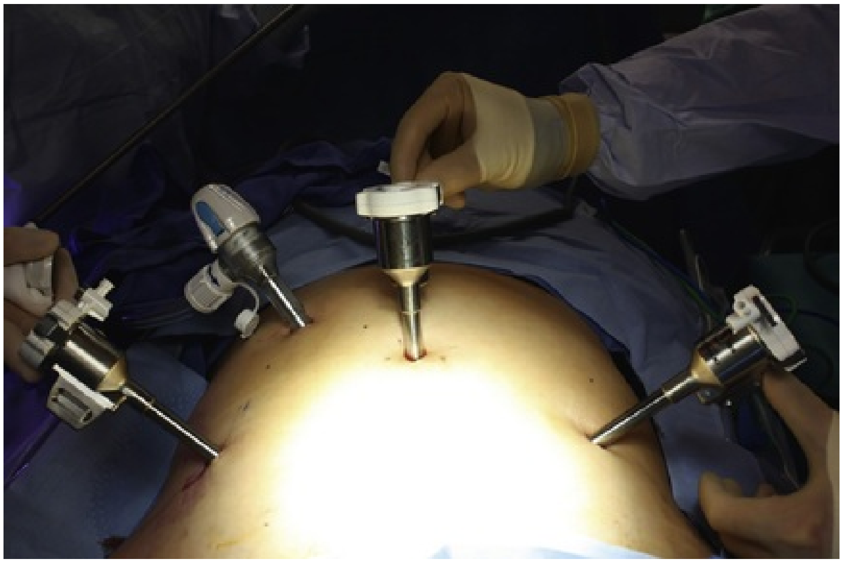

FIG. 124.23 Robotic trocar placement in a W fashion. (Courtesy Barry Hallner, LSU Department OB/GYN 2017.)

After any necessary adhesiolysis, the bowel is gently swept out of the pelvis and above the pelvic brim. The aortic bifurcation and iliac vessels are identified, and the sacral promontory is visualized and delineated at the midline (Fig. 124.24). Next the ureters are identified along the pelvic side walls, especially the right ureter, which is close to the area of dissection. An incision is made in the peritoneum over the sacral promontory, extending inferiorly along the right lateral aspect of the rectum toward the cul-de-sac, creating peritoneal leaves that will be used to retroperitonealize the graft (Fig. 124.25). Electrocautery is used when dividing the fatty tissue over the promontory to minimize bleeding and improve visualization. Careful dissection in this area is essential to avoid shearing of presacral veins because severe bleeding may occur. It is equally important to avoid the left common iliac vein, which is not infrequently located more medial than the artery and can be injured during exposure of the promontory (Good et al., 2013). The middle sacral vessel traverses over the promontory and should also be avoided. As the fatty tissue is dissected free, the anterior surface of the sacral promontory is visualized, usually by identification of the anterior longitudinal ligament (Fig. 124.26).

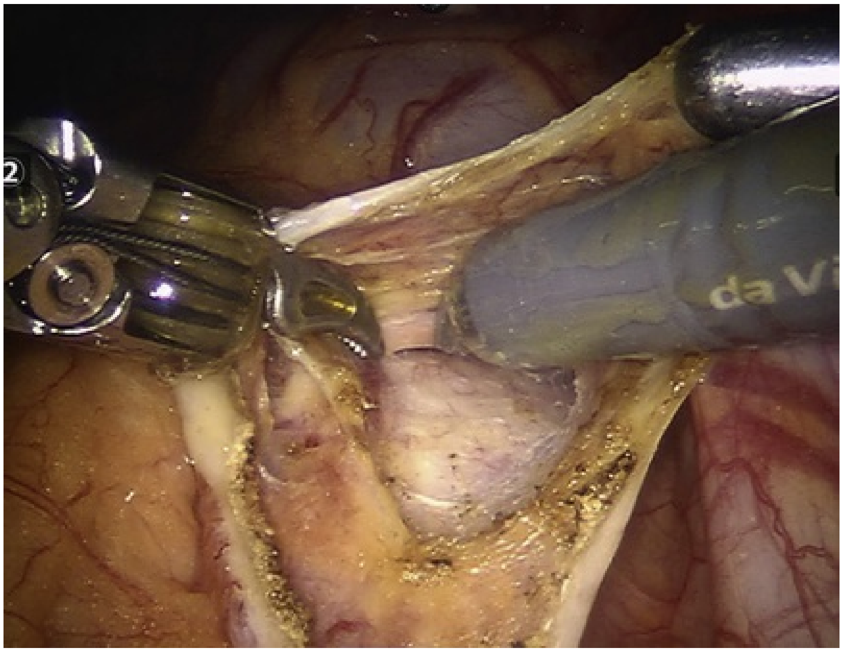

FIG. 124.26 Anterior longitudinal ligament. (Courtesy Barry Hallner, LSU Department OB/GYN 2017.)

The peritoneum incision is extended along the right pelvic side wall into the Douglas cu-de-sac. The upper vagina and vaginal apex must be elevated and distended with a vaginal stent. This permits adequate dissection and visualization of the fibromuscular layers of the vaginal wall and aids in graft placement. The vaginal stent may be a large end-to-end anastomosis sizer, a Lucite Stent (Marina Medical, Sunrise, FL), or the Colpassist Vaginal Positioning Device (Boston Scientific, Marlborough, MA). The vagina is elevated via the vaginal stent, and the peritoneum covering the vagina is incised transversely. Sharp and blunt dissection is used to separate the peritoneum and bladder from the anterior vaginal wall. This anterior dissection extends approximately 6 to 8 cm caudally to create an adequate site for graft fixation (Fig. 124.27).

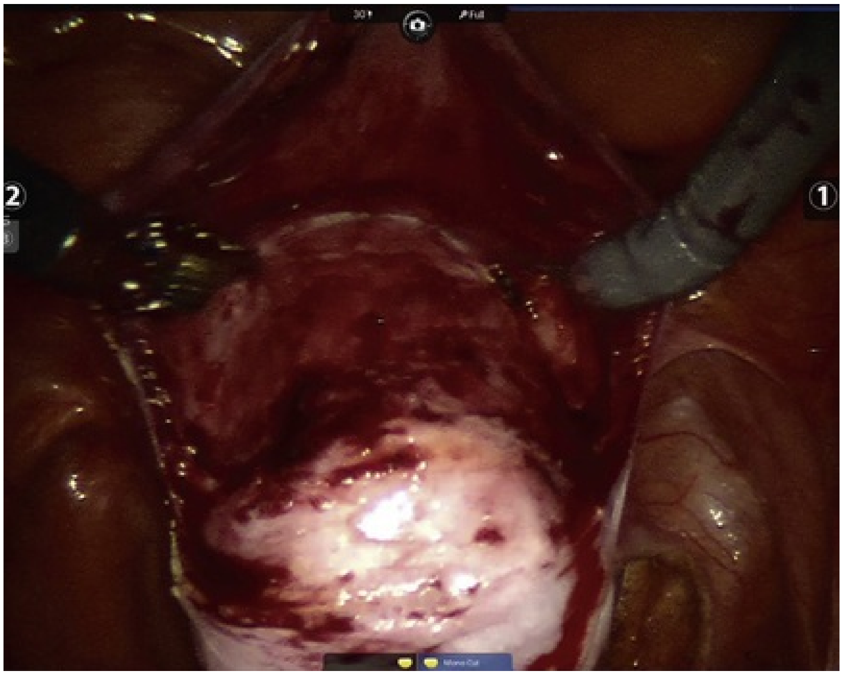

FIG. 124.27 Dissection of anterior vesicovaginal space. (Courtesy Barry Hallner, LSU Department OB/GYN 2017.)

Dissection should progress just above the fibromuscular layer in the loose areolar tissue of the vaginal wall. Dissecting in the appropriate plane decreases the risk of accidental entry into the vagina. Unintentional entry into the vaginal lumen increases the risk of future graft exposure especially when using synthetic mesh. If the vaginal wall is opened, it should be irrigated copiously followed by a two-layer closure with 2-0 or 3-0 delayed absorbable suture. Vaginal apex is redirected anteriorly, and the peritoneum covering the posterior wall is open. The rectovaginal spaces identified, and blunt dissection further opens this space to the level of the rectal reflection for distance of about 9 cm (Fig. 124.28).

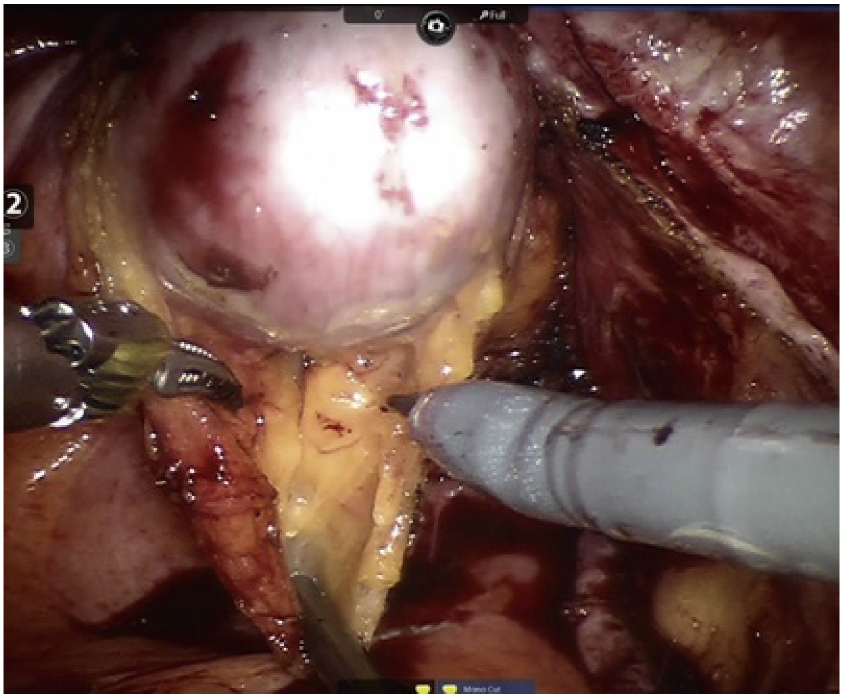

FIG. 124.28 Dissection of the posterior rectovaginal space. (Courtesy Barry Hallner, LSU Department OB/GYN 2017.)

If a sacrocolpoperineopexy is planned, dissection continues beyond the rectal reflection to the level of the perineal body (Reddy et al., 2011). The selection of the sacrocolpopexy graft is a preference of the surgeon, in general if using synthetic mesh it should be lightweight, flexible, and porous (Brown et al., 2015). Most often a prefabricated Y-shaped mesh is employed. The Y-shaped mesh is tapered and cut to the surgeon's preference. Once the initial dissection has been performed, the robotic instruments are switched to robotic needle drivers with the addition of a bowel-safe grasper. The mesh is passed into the peritoneal cavity via the assistant's trocar and guided into place. The graft may be secured to the anterior and posterior vaginal walls with delayed absorbable or permanent monofilament suture or a combination of both (Fig. 124.29). The suture is placed in full-thickness fashion without entering the vaginal lumen. Studies have shown equivalent long-term outcomes with the use of absorbable suture compared with permanent suture for sacrocolpopexy mesh fixation (Shepherd et al., 2010).

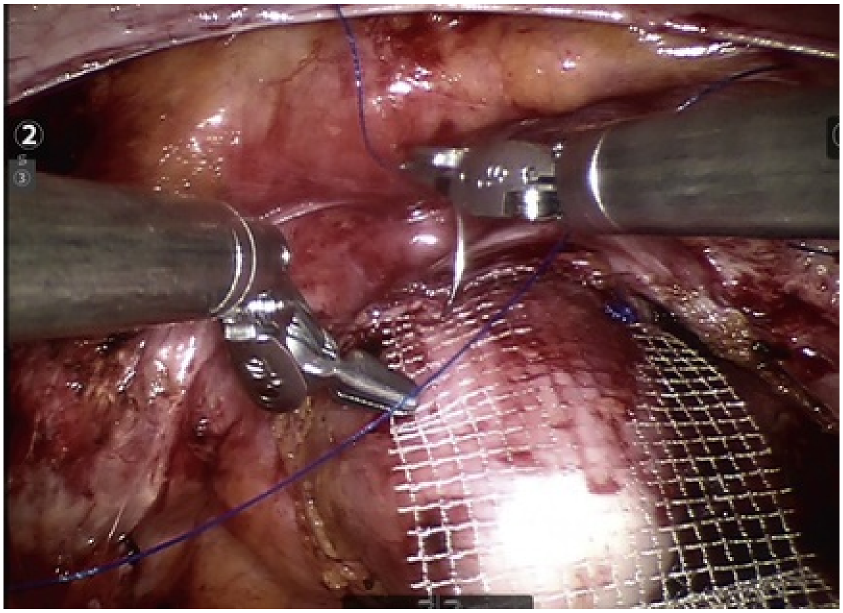

FIG. 124.29 Graft fixated to anterior and posterior vaginal wall. (Courtesy Barry Hallner, LSU Department OB/GYN 2017.)

The vaginal stent is then directed posteriorly toward the promontory and maximally extended cephalad. Tension on the stent is then released, allowing the apex to lie in a normal apical position with the prolapse reduced. Excessive tension should be avoided because it can result in pain or de novo stress urinary incontinence (Nygaard et al., 2013a,b). Tension can be performed through visual or direct vaginal examination techniques depending on surgeon preference and experience. The apical suspension should reduce the prolapse of the apex as well as the segments of the anterior and posterior vaginal walls. The tail of the graft is sutured to the anterior longitudinal ligament at the level selected by the surgeon. Traditionally sutures are placed at the S1 vertebral body or at the level of the sacral promontory (Nygaard et al., 2004a,b). Suture placement at S3 or S4 vertebral body increases the risk of injury to the presacral venous plexus, whereas placement sutures at the upper portion of the sacral promontory risks laceration of the middle sacral vessel or the left common iliac vein (Wieslander et al., 2006). However, at the level of S1 the middle sacral vessels are readily visible and can be easily isolated and avoided; two to three monofilament permanent sutures are used to fixate the graft to the anterior longitudinal ligament. The peritoneum is closed over the vaginal apex with delayed absorbable suture and continued to the level of the promontory (Fig. 124.30). The graft is now completely retroperitonealized. Cystoscopy is performed to rule out injury to the bladder, intravesical suture, or mesh perforation and to confirm ureteral patency. The robot is undocked, the patient is taken out of Trendelenburg position, the CO_2 gas is removed from the abdomen, the trocars are removed under direct vision, and trocar sites are closed according to surgeon preference.

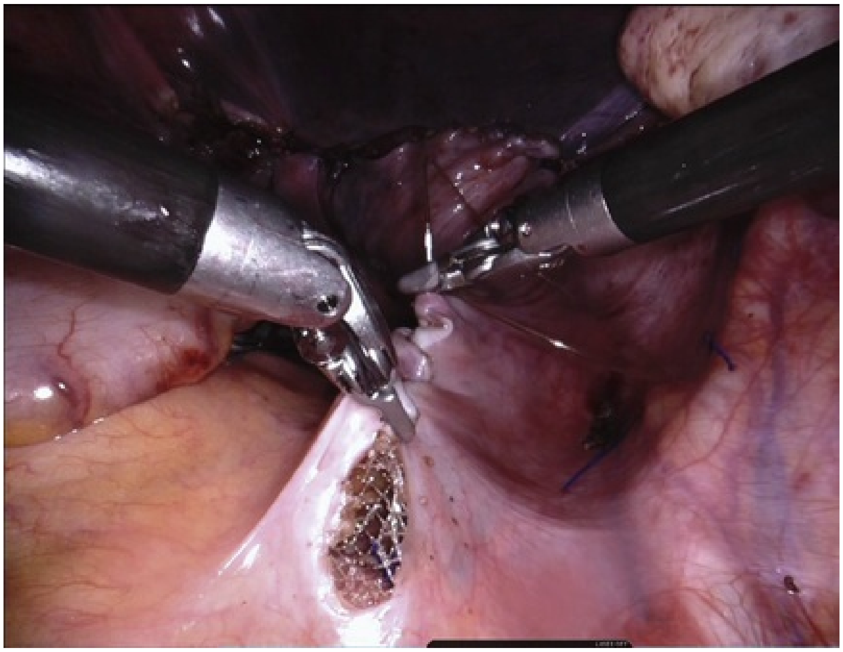

FIG. 124.30 Peritoneum is closed to the level of the promontory. (Courtesy Barry Hallner, LSU Department OB/GYN 2017.)

Laparoscopic Sacrocolpopexy Technique.

As stated earlier, sacrocolpopexy may be performed with a minimally invasive technique using laparoscopy or robotic surgery. After administration of general anesthesia, the patient is properly positioned in Allen stirrups in low lithotomy position, the arms are properly tucked to the side, and all bony prominences are padded, a pelvic exam is performed, the abdomen and vagina are surgically prepared, and a Foley catheter is inserted into the bladder. Trocar placement begins with entry into the abdominal cavity via the technique with which the surgeon is most experienced. The abdomen is inflated with CO_2 gas once entry into the abdomen is confirmed. A 0-degree laparoscope is inserted through the umbilical trocar and careful inspection of the peritoneal cavity is performed, delineating all the pertinent anatomy to performing the sacrocolpopexy. Depending on the anatomy and whether adhesiolysis is necessary, trocar placement can be performed.

There are many variations of trocar placement described, but in general trocar placement involves two additional trocars placed under direct visualization in the right and left lower quadrants, lateral to the inferior epigastric vessels, and one or two additional 5-mm ports are placed at the level of the umbilicus, lateral to the rectus muscle. Additional 5-mm trocar ports can be placed on the principal surgeon's side so that he or she can operate with two hands. Port placement is similar to robotic trocar placement and is shown in Fig. 124.23. Commonly used instruments are a unipolar scissors, bipolar cautery graspers, and laparoscopic blunt-tipped dissectors.

The patient is placed in Trendelenburg position, and the bowel is gently swept out of the pelvis. In a similar fashion as described in the robotic sacrocolpopexy section, the vagina is elevated via the vaginal stent, and the peritoneum covering the vagina is incised transversely. Sharp and blunt dissection is used to separate the peritoneum and bladder from the anterior vaginal wall. This anterior dissection extends approximately 6 to 8 cm caudally to create an adequate surface for graft fixation (see Fig. 124.27). Dissection should progress to the depth just above the fibromuscular layer of the vaginal wall. Dissecting in the appropriate plane will decrease the risk of accidental entry into the vagina. As stated earlier, if the vaginal wall is opened, it should be irrigated copiously followed by a two-layer closure with 2-0 or 3-0 delayed absorbable suture. The vaginal apex is redirected anteriorly, and the peritoneum covering the posterior wall is open. The rectovaginal spaces are identified, and blunt dissection further opens this space to the level of the rectal reflection for distance of about 7 to 9 cm. To avoid injury to the rectum, care is taken not to detach the perirectal fat tissue from the rectum.

Once the anterior and posterior dissections have been performed, the presacral dissection can begin. The sigmoid is retracted to the left. The peritoneum overlying the sacral promontory is elevated and opened on the right side of midline in a longitudinal fashion with laparoscopic scissors and extended to the cul-de-sac. The peritoneum is excised superficially and parallel to the sigmoid to create the retroperitoneal leaves that will be used later to cover the mesh. The loose fatty adipose tissue is dissected until the anterior longitudinal ligament is exposed. Care is taken to avoid the presacral vessel and the middle sacral vessels. Bleeding during the dissection is encountered; coagulation or clips can be used to achieve hemostasis. A lightweight, macroporous, polypropylene, prefabricated Y mesh can be used and is cut to surgeon preference. Alternatively, some surgeons may prefer to use individual stripes of mesh. For suturing, the surgeon determines the needle holder preference. Extracorporeally knot tying with either an open-ended or closed-ended knot pusher depends on surgeon preference. Some surgeons have chosen to avoid that tying altogether by securing the mesh for the barbed suture (V-Loc, Covidien/Medtronic, Minneapolis, MN, and Quill, Angiotech, Vancouver, BC). The mesh is passed into the peritoneal cavity via the assistant's trocar and guided into place. The graft may be secured to the anterior and posterior vaginal wall with delayed absorbable or permanent suture or a combination of both (see Fig. 124.29). The suture should incorporate the full thickness of the vaginal wall without entering the vaginal lumen. The sutures are tied extracorporeally or intracorporeally. As noted earlier, studies have shown equivalent long-term outcomes with the use of absorbable suture compared with permanent suture for sacrocolpopexy mesh fixation (Shepherd et al., 2010).

The vaginal stent is then directed posteriorly toward the promontory and maximumly extended cephalad. Tension on the stent is then released, allowing the apex to lie in a normal apical position with the prolapse reduced. Excessive tension can result in pain or de novo SUI (Nygaard et al., 2013a,b). Tension can be achieved through visual or direct vaginal examination techniques, depending on surgeon preference and experience. The apical suspension should reduce prolapse of the apex as well as the apical segments of the anterior posterior vaginal wall. The apical tail of the graft is sutured to the anterior longitudinal ligament at the level of S1 with two or three permanent monofilament sutures; alternatively titanium tacks can also be used to attach the mesh to the anterior longitudinal ligament sacrum. Currently, tacking devices are not commonly used in sacrocolpopexy as lumbosacral osteomyelitis and spondylodiscitis have been reported and are a rare but devastating complication. These rare cases have been reported in the literature, and most are related to suture or tack placement in the presacral space (Collins et al., 2011; Grimes et al., 2012; Muffly et al., 2010; Nosseir et al., 2010; Roth and Reight, 2012).

The peritoneum is closed over the vaginal apex with delayed absorbable suture and continued to the level of the promontory (see Fig. 124.30). Once the graft has been retroperitonealized, cystoscopy is performed to rule out injury to the bladder, intravesical suture, or mesh perforation and to confirm ureteral patency. The patient is taken out of Trendelenburg position, the CO_2 gas is removed from the abdomen, the trocars are removed under direct vision, and trocar sites are closed according to surgeon preference.

Sacrocolpopexy Complications.

In a comprehensive review by Nygaard et al. (2004a,b), intraoperative complications of sacrocolpopexy included hemorrhage or transfusion 4.4%, cystotomy 3.1%, enterotomy 1.6%, and ureteral injury 1.0%. Postoperative complications included urinary tract infection 10.9%, wound infection 4.6%, ileus 3.6%, deep venous thrombosis or pulmonary embolism 3.3%, and small bowel obstruction 1.1%. Significant hemorrhage may occur from disruption of the presacral vessels, and the occurrence of this complication may be reduced when fixation of the graft is performed higher on the sacral promontory. Dealing with these vessels preemptively with bipolar energy, especially with a minimally invasive approach, may preclude this complication. The CARE trial data reveal that the rate of reoperation for gastrointestinal complications with this procedure is 1.2% (Whitehead et al., 2007). Vaginal exposure of mesh is another complication and is heralded by persistent pain, discharge, or infections, and clinicians must be vigilant in follow-up (Karlovsky et al., 2005).

In meta-analysis, mesh exposure into the vagina has been reported at a rate of 3.4% to 5.4% and may vary depending on the type of mesh used (Brizzolara and Pillai-Allen, 2003; Nygaard et al., 2004a,b). Symptoms develop on average 14 months after surgery and classically consist of vaginal bleeding and discharge (Kohli et al., 1998). Exposures occur more often with Teflon or Gore-Tex–type materials and are less frequent with macroporous, monofilament meshes. Surgeons performing these procedures should be aware of the recently reported 9.9% mesh exposure rate from the extended follow-up of the multicenter CARE trial (Nygaard et al., 2013a,b). Several authors have suggested that hysterectomy at the time of colpopexy increases the rate of mesh extrusion, although these findings are not uniform (Marinkovic, 2008; Nygaard et al., 2004a,b), and no randomized trials address this issue (Nygaard et al., 2004a,b). In 60 patients undergoing concomitant hysterectomy using a two-layer closure of the vaginal cuff followed by ASC with synthetic nonabsorbable monofilament mesh, the exposure rate was 0.8% compared with 0 in the 64 patients with a prior hysterectomy (Wu et al., 2006). In patients undergoing a combined operation, supracervical hysterectomy or a meticulous two-layer closure of the cuff should be performed to decrease the incidence of mesh exposure.

Surgeons must be aware that the incidence of mesh exposure after ASC is higher after a total hysterectomy. **In patients needing hysterectomy, the feasibility of a supracervical hysterectomy should be strongly examined. In this scenario, a supracervical hysterectomy in conjunction with the ASC is**

preferred. These patients should also be informed that for uterine prolapse, a vaginal hysterectomy with vaginal vault suspension is an effective option as well. Options for the management of exposed mesh after colpopexy may include transvaginal mesh excision with or without partial colpocleisis (Quiroz et al., 2008) and abdominal mesh excision.

Results of Sacrocolpopexy.

ASC maintains a functional vagina and restores maximal vaginal length and support. In a comparative study, vaginal length was longer after ASC compared with sacrospinous fixation (Given et al., 1993). A nonabsorbable monofilament synthetic mesh should be used during ASC. In a study by Culligan et al. (2005), patients undergoing ASC were randomized to either absorbable cadaveric fascia lata graft (Tutoplast) or nonabsorbable monofilament polypropylene. The objective failure rate for recurrence at any other vaginal site was 14 out of 44 in the fascial group and 4 out of 45 in the mesh group (Culligan et al., 2005).

Numerous reports by multiple authors confirm the success of ASC using mesh, and multiple authors have reported success rates greater than 90% (Addison and Timmons, 1993; Addison et al., 1985; Cundiff et al., 1998; Nygaard et al., 2013a,b; Snyder and Krantz, 1991; Webb et al., 1998). In addition, there are several randomized, prospective trials comparing SSLF with abdominal sacrocolpopexy. In a comparative study between ASC versus vaginal repair, Benson et al. (1996) reported a lower success rate with vaginal repair and an equivalent hospital stay between the two groups. Lo and Wang (1998) reported on their results of ASC versus SSLF at a duration of 2.1 years: 94.2% success in ASC compared with 80% SSLF. Maher et al. (2004a) reported on a comparative study between ASC and SSLF. At 2 years' follow-up, symptoms and anatomic success were equivalent, but asymptomatic failures to the introitus and recurrent cystoceles were less after ASC.

Overall, vaginal (SSLF) procedures have a higher rate of recurrent anterior defects even when performed in the setting of a concomitant anterior colporrhaphy (Holley et al., 1995). After an isolated abdominal repair of vaginal vault prolapse without addressing concomitant pelvic floor defects, recurrent distal defects such as cystocele and rectocele may occur up to one-third of the time. This may predispose to decreased patient satisfaction and the possibility of secondary vaginal repair (Blanchard et al., 2006). Although most remain asymptomatic, secondary repair of these defects may be required (Blanchard et al., 2006). It is important to counsel patients preoperatively about the possibility of distal anterior or posterior defects after ASC, and the need for secondary vaginal repair, which can occur up to 20% of the time (Blanchard et al., 2006). In 2013 the extended CARE trial showed that at 7 years after ASC the recurrence rate of POP progressively increases. The anatomic treatment failure (C > tvl-2 or Ba/Bp > +1) rates for ASC with and without Burch urethropexy were 0.27 and 0.22, respectively. Interestingly, half of these were asymptomatic. The symptomatic failures were between 29% and 24%, anatomic failure rates were between 27% and 22%, and composite rates of failure were 48% and 34% for their 2 groups. However, half of these patients were not retreated (Nygaard et al., 2013a,b).

Rozet et al. (2005) reported on 363 patients who underwent laparoscopic sacrocolpopexy (LSC) between 1996 and 2002. Their mean age was 63 (range 35–78), average follow-up was 14.6 months, and the mean operating time was 97 minutes. Follow-up was a postal questionnaire and physical examination at 6 months and then yearly; 96% were satisfied with the results of their operation, and no patients complained of sexual dysfunction. There was a 4% recurrence rate of prolapse, 3 vaginal erosions, 2 urinary retentions that required TVT resection, 1 bowel incarceration, 1 spondylitis, and 2 mesh infections (Rozet et al., 2005; Tables 124.7 and 124.8).

Claerhout et al. (2009) reported a prospective series of 132 women that underwent LSC between 2001 and 2006. The mean follow-up was 12.5 months with a mean operative time of 180.5 minutes. The objective cure rate was 98%, and a 18% failure rate was seen mainly in the posterior compartment, although no patient underwent reoperation. De novo SUI was noted in 7.4% of patients postoperatively. Mesh erosion was seen in 4.5% of patients, all within 1 year; 2.7% of patients experienced mesh-related pain (Claerhout et al., 2009) (see Tables 124.7 and 124.8).

In a 2014 review of robotic and LSC, Lee at al. (2014) reported results from 11 patient series encompassing 1221 patients with a mean follow-up of 26 months. Mean operative time was 124 minutes (range 55–185) with a 3% (range 0–11%) conversion rate. Objective cure was achieved in 91% of patients and similar satisfaction rates of 92% (Lee et al., 2014). Only a few well-designed comparative studies exist, and many have varying objective and subjective outcomes. A total of five studies compared the outcomes of LSC with ASC. Most are short term, with a mean follow-up of 12 months or less.

Abdominal Sacrocolpopexy Versus Laparoscopic Sacrocolpopexy (Table 124.9).

Recently Coolen et al. (2017) randomized 73 women with a history of hysterectomy who had symptomatic vaginal vault prolapse, with or without concomitant cystocele and rectocele, to either ASC or LSC. The mean follow-up was 12 months. The primary outcome of the study was functional outcome, which was evaluated using the UDI. The questionnaires also contain versions of the Defecatory Distress Inventory (DDI), the Incontinence Impact Questionnaire (IIQ), the PGI-I, and questions about sexuality, which were secondary outcomes. Secondary outcomes included procedure time, amount of estimated blood loss, hospital stay, perioperative complications, reinterventions, composite outcome of success (defined as no prolapse beyond the hymen), no bothersome bulge symptoms, and no repeat surgery or pessary use for recurrent prolapse within 12 months and long-term complications. The composite outcome of success was 83.8% (31 out of 37) for the laparoscopy group and 89.2% (33 out of 37) in the open abdominal group. In both groups, there were no recurrences of stage 2 or higher of the apical compartment. Two patients in the laparoscopy group had bothersome bulge symptoms compared with 4 in abdominal group. Five participants of the laparoscopy group had additional surgery for POP, versus 1 in the abdominal group. In both groups more participants became sexually active, there was less dyspareunia, and the coital frequency was increased at 12 months postoperatively. There are no significant differences between the groups.

ASC, Abdominal sacrocolpopexy; *LSC,* laparoscopic sacrocolpopexy; *PGI-I,* Patient Global Impression of Improvement; *POP-Q,* pelvic organ prolapse-quantification.

Freeman et al. (2013) compared abdominal sacrocolpopexy with laparoscopic sacrocolpopexy in a multicenter randomized equivalence trial for treatment of post-hysterectomy vaginal vault prolapse. Patients were included if they had at least a stage 2 vaginal vault prolapse and did not need additional prolapse procedures. The primary outcomes were location of POP-Q point C and PGI-I scores at 1 year of follow-up (see Table 124.9). Secondary outcomes were intraoperative blood loss, mean drop in hemoglobin, length of postoperative hospitalization, operating time, postoperative pain assessment, return to daily activities, QoL, new onset of urinary incontinence, and reoperation rates. At 1 year, point C met equivalence criteria for the abdominal and laparoscopic groups (6.63 ± 1.4 cm and 6.65 ± 1.2 cm, respectively; $P > 0.050$). In addition, 90% of patients in the abdominal group and 80% of those in the laparoscopic group responded that they were either “very much better” or “much better” on the PGI-I at 1 year postsurgery. There was a lower blood loss (56.2 ± 34 vs. 240.4 ± 232 mL; $P < 0.01$), and a shorter length of hospital stay (3.2 ± 1.1 vs. 4.1 ± 1.6 days; $P = 0.02$) in the laparoscopic group. Interestingly, operative times did not differ between the abdominal and laparoscopic groups (131 ± 44 vs. 144 ± 28 min, respectively; $P = 0.24$). Although there was higher postoperative morphine use in the abdominal group, physical function scores at 1 week postoperatively on question 3 of the SF-36 did not differ between surgery groups (Freeman et al., 2013).

Geller et al. (2008) reported results of a retrospective cohort of 178 patients (73 robotic and 105 abdominal sacrocolpopexy). The primary outcome was vaginal vault support on postoperative POP-Q system examination. Secondary outcomes included blood loss, operative time, length of stay, blood transfusion, pulmonary embolus, gastrointestinal or genitourinary tract injury, ileus, bowel obstruction, postoperative fever, pneumonia, wound infection, and urinary retention. Robotic-assisted sacrocolpopexy (RSC) showed slight improvement on POP-Q “C” point (−9 compared with −8, $P = 0.008$) when compared with ASC and was associated with less blood loss (103+/−96 mL compared with 255+/-155 mL, $P < 0.001$). RSC had a longer total operative time (328+/−55 minutes compared with 225+/−61 minutes, $P < 0.001$), shorter length of stay (1.3+/−0.8 days compared with 2.7+/−1.4 days, P < 0.001), and a higher incidence of postoperative fever (4.1% compared with 0.0, $P = 0.04$). There were no gastrointestinal tract injuries, and there was one cystotomy in each surgery group ($P = 1.0$) (Geller et al., 2008).

Laparoscopic Sacrocolpopexy Versus Robotic-Assisted Sacrocolpopexy Versus Abdominal Sacrocolpopexy (Table 124.10).

Nosti et al. (2009) presented a multicenter retrospective cohort trial comparing perioperative and postoperative surgical outcomes between open and minimally invasive sacrocolpopexy in 831 women who underwent surgery between 1999 and 2009. Anatomic failure was defined as POP-Q stage of at least stage 2. Four hundred patients in the cohort underwent open sacrocolpopexy, 231 underwent laparoscopic, and 218 had RSC. Laparoscopic and robotic cases were analyzed as minimally invasive sacrocolpopexy. Anatomic failures were higher in the open group compared with the minimally invasive group (24.1% vs. 14.3%; $P < 0.01$), which was predominantly because of posterior support. Compared with women who underwent minimally invasive sacrocolpopexy, women undergoing open sacrocolpopexy had a higher operative blood loss (188 vs. 122 mL; $P < 0.01$), longer hospital stay (2.8 vs. 1.2 days; $P < 0.01$), and longer operative times (234 vs. 206 min; $P < 0.01$), despite fewer concomitant procedures in the open group (1.5 vs. 2.0; $P < 0.01$). **In a comparison of traditional and robotic sacrocolpopexy, robotic cases had fewer anatomic failures (5.9% vs. 18.9%; $P < 0.01$), despite more advanced preoperative prolapse in the robotic**

group.

Laparoscopic Sacrocolpopexy Versus Robotic-Assisted Colpopexy.

Paraiso et al. (2011) randomized women with stage 2 to 4 post-hysterectomy vaginal apex prolapse to either LSC or RSC. The primary outcome was total operative time from incision to closure, but secondary outcomes included postoperative pain, functional activity, bowel and bladder symptoms, QoL, anatomic vaginal support, and cost from a health care perspective. Total operative time was significantly longer in the robotic group (227 +/−47 versus 162 +/−47 min; $P < 0.001$), with docking only accounting for an average of 14 additional minutes. Robotic suturing tying was longer (98 +/−22 vs. 68 +/−16 min; $P < 0.001$). Although pain scores were not significantly different on postoperative day 1, the robotic group reported more pain at rest and with normal activities at several points during the 6-week postoperative period. The authors thought the increase in pain was due to manipulation and fascial closure of the right paracolic gutter accessory port; they have since changed the port size to an 8-mm port. At 6- and 12-month follow-up, anatomic and QoL outcomes did not differ between the two groups (see Table 124.10).

Antosh et al. (2012) reported intraoperative and postoperative complications in their retrospective cohort comparison of RSC ($N = 65$) and LSC ($N = 23$). Median preoperative prolapse was stage 3 for both groups. There was no statistically significant difference in the median operative time between the RSC and LSC groups, although this did not include robot setup time and did include concurrent procedures that differed significantly between groups (334 vs. 325 minutes, *P* = 0.30). Estimated blood loss was lower in the robotic group (50 vs. 100 mL, *P* = 0.003). There were no differences in overall objective cure rates between RSC and LSC groups at 3 months of follow-up (87.1% vs. 91.3%, *P* = 0.72). Perioperative complications, including visceral injury and mesh erosion, did not differ significantly between these groups (Antosh et al., 2012) (see Table 124.10).

Long-term success and complication data from well-designed studies for sacrocolpopexy are limited. In 2013 the E-CARE trial reported that 7 years after open ASC, symptomatic failure was between 29% and 24%; anatomic failure rates were between 27% and 22%; and composite rates of failure were 48% and 34% for their 2 groups. Unger et al. (2017) reported results of a retrospective study of 1381 women undergoing uterosacral colpopexy, LSC, and RSC for treatment of POP between 2006 and 2012: 983 patients (71.1%) underwent USC, 256 (18.5%) patients underwent LSC, and 142 (11.2%) patients underwent RSC. Follow-up ranged from 1 to 28 months with median (interquartile range) follow-up time for each group: uterosacral colpopexy, 6.2 (1.5–27.6) months; laparoscopic sacrocolpopexy, 5.8 (1.9–13.5) months; robotic sacrocolpopexy, 5.8 (2.8–13.8) months. The interesting aspect of this study, however, was that the authors were able to extrapolate long-term outcomes. Median (range) months to failure were 17.1 (7.6–41) months for uterosacral colpopexy, 10.1 (4.7–25.1) months for LSC, and 9.7 (1.6–17.2) months for RSC. Rates of retreatment for POP were 14%, 8%, and 23% for uterosacral colpopexy, LSC, and RSC, respectively. In the RSC cohort, 86% of retreatment for POP was for symptomatic rectocele, and 14% were for symptomatic cystocele. In the LSC group, 67% were for symptomatic rectocele, and 33% were for symptomatic cystocele.

There were no retreatments for apical prolapse in the RSC or LSC groups. Authors suggest by year 6, using strict composite definitions, the estimated recurrence rates for the uterosacral colpopexy, RSC, and LSC may be as high as 40% to 60% (Unger et al., 2017). The majority of patients receiving uterosacral colpopexy were primary prolapse repairs, whereas up to 40% of the laparoscopic and robotic cases had undergone previous POP surgery. When baseline risk factors (such as previous POP surgery and concomitant rectocele repair) for recurrent POP were controlled for, uterosacral colpopexy appeared to have a higher risk of anatomic recurrent POP but a lower risk of symptomatic bulge and need for retreatment for POP when compared with RSC and LSC (Unger et al., 2017). In a meta-analysis of outcomes after robotic sacrocolpopexy, Hudson et al. (2014) found that the most common reason for reoperation after RSC was recurrent prolapse with a combined estimated rate of 3.3% (95% CI 1.4–5.2) with the majority being posterior repairs for non-apical prolapse.

Learning Curve.

Mustafa et al. (2012) described the LSC learning curve with a retrospective review of 47 consecutive women undergoing LSC at a single tertiary care medical center. Mean operative time significantly decreased from 196 to 162 min when comparing the first 15 versus the last 30 cases. Blood loss and complication rates were unchanged. The authors asserted that approximately 30 to 40 cases were necessary to master LSC. This experience was echoed by Claerhout et al. (2009), who noted an inflection point in the duration of surgery after 18 to 24 cases. A learning curve for RSC also exists. Germain et al. (2013) reported on 52 patients undergoing RSC over a 7-year period (Tables 124.11 and 124.12). Mean operative time decreased from 222 min during the first 10 cases to 183 for the next 10 cases. Lenihan et al. (2008) also reported that the learning curve for RSC comprised about 50 cases. A summary of clinical outcomes of RSC case series may be found in Tables 124.11 and 124.12.

Cost.

The cost of minimally invasive prolapse surgery has been compared with open, vaginal, laparoscopic, and robotic procedures. Surgical costs can be calculated in several different ways; consequently, comparison of cost data can be difficult (Tarr and Paraiso, 2015). Judd et al., in a 2010 cost-minimization analysis comparing RSC, LSC, and ASC, noted that RSC was the most expensive, $8508 per procedure when compared with LSC at $7353 and ASC at $5792. RSC and LSC became cost-equivalent only when robotic operative time was reduced to

149 minutes. In the Paraiso et al., 2011 study, it was reported that RSC cost more than laparoscopic sacrocolpopexy ($16,278 ± $3326 vs. $14,342 ± $2941, respectively), with a mean difference of +$1936 (95% CI $417–$3454; *P* = 0.008). The cost discrepancy was mainly driven by the difference in operating room costs (MD +$1667; 95% CI $448–$2885; *P* = 0.008). The cost analysis did not account for the initial robot purchase or yearly maintenance (Paraiso et al., 2011). In a 2012 cost-minimization analysis performed in a retrospective cohort of patients who had undergone either RSC or open sacrocolpopexy at Stanford, it was determined that base case analysis revealed an overall 10% cost savings for RSC versus open sacrocolpopexy ($10,178 vs. $11,307). Elliot's Tornado analysis suggested that the number of institutional robotic cases done annually, length of stay, and cost per hospitalization day in the postoperative period were the largest drivers of cost (Elliott et al., 2012).

Comparison of Apical Procedures

In a 2016 Cochrane review of surgery for apical vaginal prolapse, vaginal procedures versus sacrocolpopexy were more likely to experience awareness of prolapse (RR 2.11, 95% CI 1.06–4.21), repeat surgery for prolapse (RR 2.28, 95% CI 1.20–4.32), recurrent prolapse (RR 1.89, 95% CI 1.33–2.70), stress incontinence (RR 1.86, 95% CI 1.17–2.94), and dyspareunia (RR 2.53, 95% CI 1.17–5.50) (Maher et al., 2016a). Vaginal procedures do have high success rates with low operation rates and may be the procedure of choice for many older women. The 2016 Cochrane review concluded that there was no evidence of any difference for any of the primary outcomes between different types of apical vaginal native tissue repairs. Likewise Siff and Barber (2016) in a comparative effectiveness trial found that SSLF and uterosacral ligament suspension were effective and provided similar outcomes in anatomy and function with few adverse events. In addition, they noted that regarding uterine preservation, sacrospinous hysteropexy was not inferior to vaginal hysterectomy with uterosacral suspension for the treatment of apical uterovaginal prolapse.

Colpocleisis

Colpocleisis is an obliterative procedure used in the treatment of post-hysterectomy vaginal vault prolapse or significant uterovaginal prolapse. In properly counseled, older patients who do not desire a functional vagina for sexual activity, colpocleisis may be an appropriate, noninvasive procedure. The total colpocleisis is performed in patients who have undergone hysterectomy and refers to removal of the vaginal epithelium to approximately 2 to 3 cm from the urethral meatus with complete closure. A partial colpocleisis is used in cases of uterovaginal prolapse. This procedure involves creating lateral channels to allow potential uterine drainage. Advantages of the colpocleisis procedures are shorter operative time, ability to use regional anesthesia or local anesthesia with sedation, minimal complications, minimal recurrence, and decreased recuperative time (Cespedes et al., 2001; FitzGerald et al., 2008). In those whose uterus is to be left in situ, preoperative evaluation should include a Papanicolaou smear, pelvic sonogram, and endometrial biopsy if indicated. Performance of hysterectomy at the time of colpocleisis eliminates the risk of developing cervical or endometrial cancer and eliminates the risk of developing pyometra, which is a serious complication of partial colpocleisis when the channels become obstructed (Shayya et al., 2009). However, most patients selected for colpocleisis are older with significant comorbidities that make a concomitant hysterectomy undesirable.

Partial Colpocleisis—Technique.

The patient is placed in standard lithotomy position. A Foley catheter is placed into the bladder. If an anti-incontinence procedure is needed, it may be performed first. The cervix is grasped with a tenaculum, and a rectangular segment of vaginal epithelium is marked anteriorly and posteriorly. The excision of the vaginal epithelium will extend 3 cm from the urethral meatus to 3 cm from the cervix (Cespedes et al., 2001). It is important to leave sufficient vaginal epithelium laterally to allow creation of the lateral channels to facilitate drainage. The epithelium is then excised. It is optional to place a 14-Fr Red Robinson catheter or a vessel loop along the vaginal sidewalls to assist in forming the channels. Then, starting at the leading edge of the prolapse, the surgeon places successive layers of 2-0 delayed absorbable sutures, which plicate and reduce the prolapse until the prolapsed tissues are above the levator plate (Fig. 124.31A). The sutures are placed in transverse rows consisting of linear sutures through the pubocervical fascia anteriorly and rectovaginal fascia posteriorly. As these sutures are tied, the apical prolapse is reduced proximally (Fig. 124.31B). Successive rows of sutures are placed until the apical prolapse is completely reduced. A high perineorrhaphy is performed by removing a triangular segment of the vaginal epithelium. The fibromuscular tissues of the perineal body are approximated in the midline with absorbable sutures to narrow the introitus. Fig. 124.32 shows the completed procedures. Indigo carmine is administered, and a cystoscopy is carried out to confirm ureteral patency.

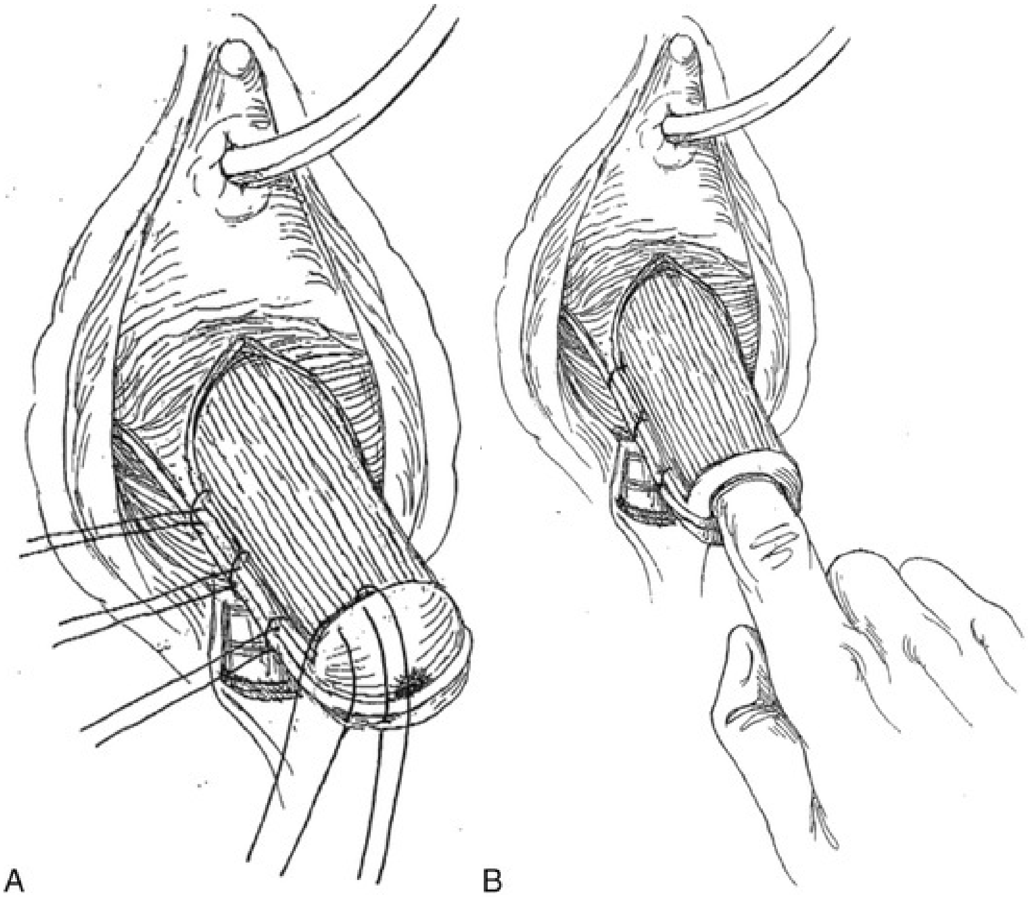

FIG. 124.31 (A) Partial colpocleisis is started by excising rectangular portions of the vaginal epithelium, leaving lateral channels. The cervix is then inverted over a Red Robinson catheter. (B) The cervix is inverted as the prolapse is reduced. (A, From Baggish M, Karram M: *Atlas of pelvic anatomy and gynecologic surgery,* ed 3, Philadelphia, 2010, Saunders, Fig 56-1, pp 724–726.)

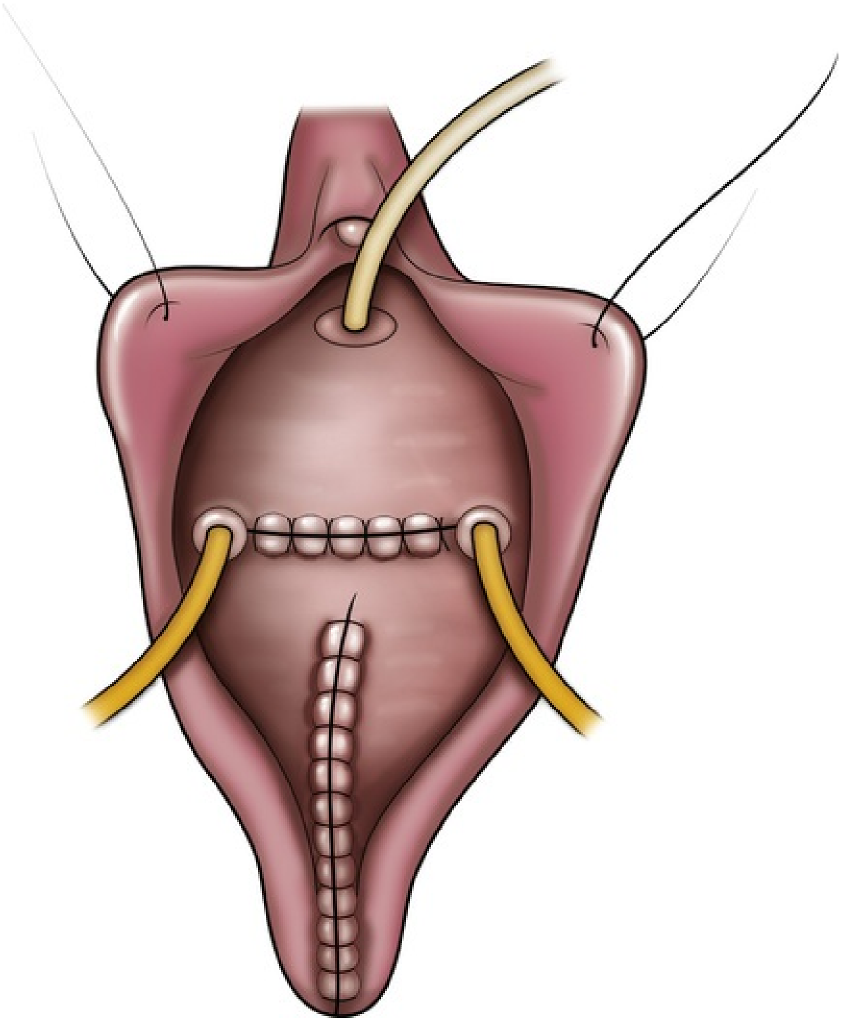

FIG. 124.32 The partial colpocleisis is completed along with perineorrhaphy. (From Cespedes RD, Winters CW: Colpocleisis for the treatment of severe vaginal vault prolapse. In Vasavada SP, Appell RA, Sand PK, et al., editors: *Female urology, urogynecology, and voiding dysfunction*. Boca Raton, FL, 2005, Taylor & Francis.)

Total Colpocleisis: Technique (Fig. 124.33).

The technique differs from partial colpocleisis in that the lateral channels are not left in place, but rather, the entire prolapsed vagina is denuded of its epithelium from the apex to 4 cm proximal to the urethral meatus (see Fig. 124.33C). The dissection is carried laterally and continued to the posterior lateral sulcus. The prolapse sac is dissected away from the vaginal epithelium. Usually the enterocele reduces easily, and no further treatment is necessary (Cespedes et al., 2001). At this point, the colpocleisis is carried out starting at the leading edge of the prolapse. Purse-string sutures of 2-0 absorbable sutures are placed circumferentially around the prolapse including pubocervical and prerectal (rectovaginal) fascia (see Fig. 124.33D). As each progressive suture is tied, the prolapse is reduced proximally (see Fig. 124.33D). These progressive purse-string sutures are carried out until the prolapse is adequately reduced. Alternatively, the prolapse may be reduced as described for the partial colpocleisis by placing transverse rows of interrupted sutures. As these rows are tied, the prolapse is reduced proximally. Successive rows of sutures are placed until the prolapse is fully reduced. The remainder of the procedure is carried out as described for the partial colpocleisis. After the prolapse is reduced, the posterior vaginal wall and perineum are repaired (see Fig. 124.33 E and F). A high perineorrhaphy (levator myorrhaphy) is important to narrow the introitus and prevent recurrence. Cystoscopy to ensure patency of the ureters is recommended. For both techniques, success depends on the amount of vaginal tissue sutured together. This creates a septum of support, which is enhanced by bringing the levator muscles together along with the perineorrhaphy.

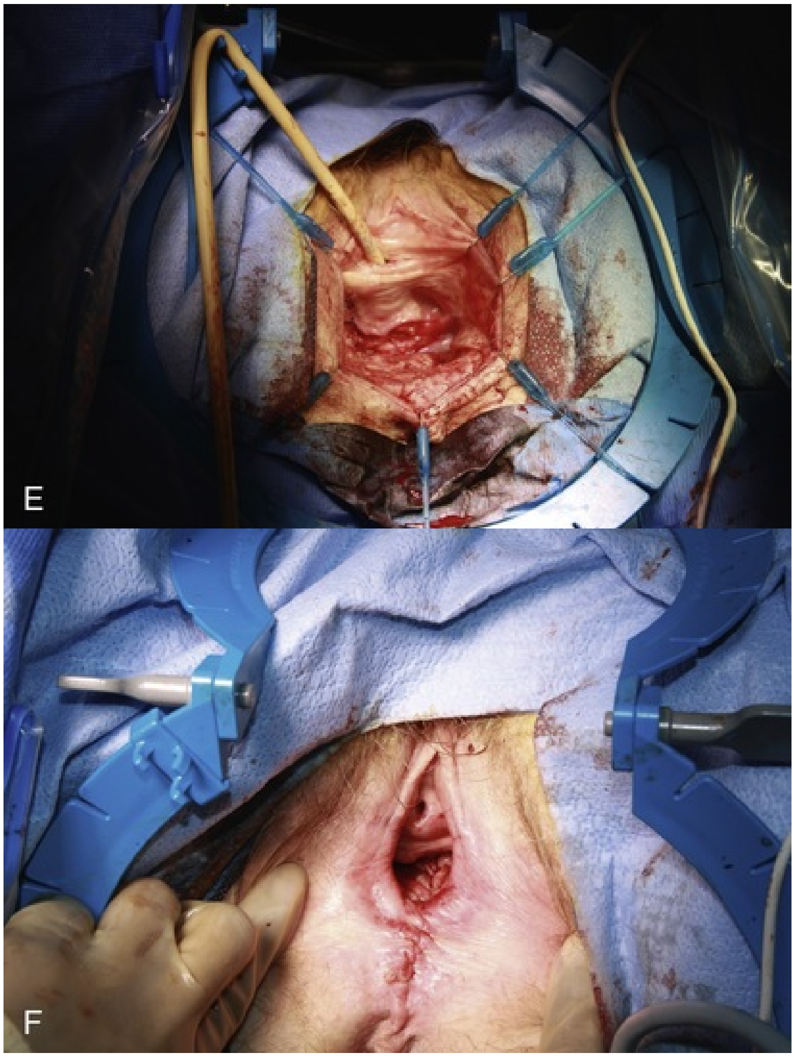

FIG. 124.33 (A) Total colpocleisis. Apex placed on tension. Anterior and lateral vaginal epithelium marked in quadrants to help maintain orientation. (B) Total colpocleisis. Posterior vaginal epithelium marked in quadrants to help maintain orientation. (C) The vaginal epithelium is removed in sections. Only the vaginal epithelium is removed, leaving as much fibromuscularis as possible behind. (D) Once the vaginal epithelium has been removed, a series of purse-string sutures are placed and the prolapse is reduced. (E) The posterior vaginal epithelium is excised to the lateral fornix, and an aggressive levatorplasty is performed. (F) Levatorplasty and perineorrhaphy are performed. The vaginal length is approximately 3 cm. (Courtesy Barry Hallner MD., LSU Department of OB/GYN/Urology 2017.)

Several authors have reported that it is unnecessary to open the enterocele sac if one is present, because the repair will close the potential space in which the bowel may protrude (DeLancey and Morley, 1997; Karin Glavind and Kempf, 2005). If the enterocele sac cannot be reduced, then purse-string absorbable sutures incorporating the sac and the uterosacral remnants can be used to reduce the sac (Cespedes, 2001).

Colpocleisis Results.

DeLancey and Morley (1997) reported on 33 women who underwent colpocleisis over a 20-year period. In this study, opening of the enterocele sac was avoided. One vaginal eversion recurrence was noted. She was treated with repeat colpocleisis and had a good response 1 year after the second colpocleisis. All but one patient expressly denied regret over the decision to have an operation that precludes the ability to have intercourse; however, one “accepted” her sexual inactivity. Many indicated relief of the discomfort associated with the prolapse and were positive about the outcome of the operation. Cespedes et al. (2001) reported on 38 patients who underwent a mean of 24 months’ follow-up. There was no recurrent prolapse. Three patients had postoperative incontinence. All were satisfied with the procedure, and no complications were noted. von Pechmann et al. (2003) reported on a large study (92 patients) who underwent colpocleisis. Patients were followed by examination and phone survey, which appraised satisfaction and regret. Regret over the loss of coital ability was expressed in 12.9% or 8 patients. In a multicenter, prospective study designed to study the effect of colpocleisis on pelvic support, symptoms, QoL, morbidity, and postoperative satisfaction, FitzGerald et al. (2006) reported on 152 patients with 1 year follow-up: 84% stated they were either very satisfied or satisfied about the decision for vaginal closure. One patient was dissatisfied, and one was very dissatisfied. One patient underwent repeat colpocleisis for recurrence. Most patients did not experience worsening of their body image. Koski et al. (2012) reported on 53 patients undergoing colpocleisis: 74% had a total colpocleisis, 91% described the procedure as successful on the PGI-I scale, and examinations correlated with these findings. Urinary frequency and urgency were the most bothersome symptoms reported in 33% of patients.

Partial Colpocleisis Results.

Goldman et al. (1981) reported on 118 patients who underwent Le Fort colpocleisis. Good anatomic results were noted in 107 patients with 101 reporting a relief of symptoms. There were 3 recurrences, but none underwent further operative therapy. Immediate postoperative complications included one pulmonary embolus, fever, and UTI. Langmade and Oliver (1986) reported on 102 patients. There were no recurrences and no de novo stress incontinence. Sixteen patients had transient postoperative urinary retention. There was no reported regret regarding the ability to engage in sexual intercourse. In a retrospective series of more than 300 women, the anatomic success rate was 98.1% with a patient satisfaction rate of 92.9%. These authors concluded that colpocleisis is an effective and low-risk procedure for the appropriate elderly patient with advanced POP (Zebede et al., 2013). In a multi-institution database search, Mueller et al. (2015) confirmed these findings. Of 4776 colpocleisis procedures, 43% done on women older than 80 years, the mean length of stay was 2.3 days and the mortality rate was 1.5%. The overall complication rate was 6.8% with a readmission rate of 4.2% (Mueller et al., 2015).

Crisp et al. (2013) reported on body image, regret, and satisfaction after LeFort and total colpocleisis. This multicenter trial confirmed the results of earlier studies, which demonstrated improved body image, improved pelvic floor symptoms, low levels of regret, and high levels of satisfaction (Crisp et al., 2013). Findings by Wang et al. (2017) were similar in their retrospective study of 287 women, yielding the same positive end results. Urinary incontinence after colpocleisis may occur and has been attributed to several mechanisms. Occult stress incontinence may be unmasked with reduction of the urethrovesical angle as described above. An alternative mechanism, secondary to traction on the urethra when it is approximated with the posterior vaginal muscularis, has been proposed (FitzGerald et al., 2006). Thus it is recommended to avoid colpectomy of at least 1.5 cm of the distal anterior vaginal wall adjacent to the urethral meatus (FitzGerald et al., 2006). As with other prolapse cases, the recommendation of a concomitant anti-incontinence procedure in an asymptomatic patient is controversial and remains to be substantiated by prospective studies. **However, it is clear that these women may develop SUI postoperatively. Thus all women before undergoing colpocleisis should be screened for the presence of occult SUI, and anti-incontinence procedures should be offered concomitantly in women with symptoms of SUI or occult SUI.** In addition, in the frail, elderly patients there is concern for urinary retention, frequently the result of impaired contractility (which may be appreciated preoperatively) and other perioperative factors. This may be more difficult to manage because these patients are more likely to be unable to perform intermittent catheterization. Thus these possibilities must be discussed with the patients in advance of surgery. Patients considered at significant risk for retention may be offered a suprapubic tube to assist in bladder management postoperatively.

Uterine Prolapse

POP is a common indication for routine hysterectomy. Although the majority of hysterectomies are performed transabdominally, the vaginal approach offers the advantages of less invasive surgery and the ability to repair concomitant pelvic floor defects (Doucette et al., 2001; Eilber and Raz, 2004).

The uterus is suspended in the pelvis by the cardinal uterosacral complex. The body of the uterus is enveloped between the two leaves of the broad ligament, which also surrounds the fallopian tube, round ligament, and ovarian ligament along with the uterine and ovarian vessels. The broad ligament does not provide significant support (Eilber and Raz, 2004). Therefore the defect prompting uterine prolapse is in the form of attenuated ligaments or specific breaks in the continuity of the cardinal uterosacral complex. Contraindications for the vaginal approach are endometriosis of unknown extent, obliteration of the cul-de-sac, large fibroids (size disproportion to the introitus), pelvic tumor, adnexal tumor, and malignancy of the uterus or ovaries (Eilber et al., 2005). If a patient has uterine prolapse, vaginal hysterectomy alone is not adequate treatment. Vaginal apex suspension should be performed at the time of hysterectomy for uterine prolapse to reduce the risk of recurrent POP; at a minimum the addition of a McCall culdoplasty should be considered. McCall (1957) highlighted this importance when he described his technique of posterior culdoplasty. This technique closed the peritoneal cul-de-sac posteriorly, thereby preventing enterocele formation and emphasized the importance of apical fixation. In this landmark paper, he described the following technique: “The posterior culdeplasty is a simple procedure which obliterates the redundant cul-de-sac of Douglas by a series of continuous sutures so as to suspend it by the uterosacral ligaments which then are brought together in the midline.”

Vaginal Hysterectomy With McCall Culdoplasty Technique

The patient is placed in dorsal lithotomy position. The type of stirrups used for the lithotomy position are at the sole discretion of the surgeon. Regardless of which type is used, careful attention is required to protect vulnerable bony, vascular, and neurologic points in the lower extremities. The patient is prepped and draped in the usual sterile fashion. A Foley catheter is placed to drain the bladder, although some surgeons may prefer not to catheterize the bladder before the anterior colpotomy to easily identify an unintentional cystotomy. Retraction of the labia and vaginal introitus with a ring retractor such as a Lone Star self-retaining retractor (CooperSurgical, Trumbull, CT) is useful. A Lahey-thyroid clamp is used to grasp the anterior and posterior lips of the cervix. Care must be taken to place the clamp on the most distal portion of the cervix, as the bladder may descend low on the anterior vaginal wall. Some surgeons find it useful to inject 1 : 200,000 epinephrine or lidocaine with epinephrine diluted in injectable saline into the vaginal wall to control small bleeding and for hydrodissection.

The cervix is placed on traction, and the initial anterior vaginal incision should be made through the full thickness of the vaginal epithelium at the border of the vaginal rugae and the smooth epithelium overline the cervix from the 10 to 2 o'clock position. The cervix is elevated outward and upward, and the posterior incision is made from the 8 to 4 o'clock position. If adequate dissent of the cervix is possible, the initial incision can be extended circumferentially around the cervix. An incision at the appropriate location allows the surgeon to avoid excessive dissection of the connective tissues between the vagina and the peritoneum and facilitates identification of the peritoneum entry. After the posterior incision has been completed, the posterior cul-de-sac and peritoneum can be readily identified with Allis clamp or tissue forceps placed on the outer edge of the incision. The Allis clamp or tissue forceps is pulled downward to create tension across the exposed posterior peritoneum. The peritoneum is cut with curved Mayo scissors and the cul-de-sac is entered. The posterior peritoneum is then affixed centrally to the posterior vaginal wall incision with the single stitch of delayed absorbable suture. Examination of the cul-de-sac can reveal further pathology, and palpation of the uterosacral ligaments can be performed. A long-bladed Steiner Auvard weighted speculum or long right-angle retractor can be introduced into the posterior peritoneal cavity. The cervix is then placed on outward and upward traction, and the uterosacral ligaments are identified by palpation, the ligament is clamped with the curved Heaney clamp, transected, and ligated with 0-gauge delayed absorbable suture using a transfection stitch. The opposite uterosacral ligament is then ligated in similar fashion.

The uterosacral cardinal ligaments may be isolated, clamped, and ligated individually or in combination depending on the size of each. Once the pedicles are secured, the free suture ends are not cut but rather held by hemostats. Clamping and tagging the uterosacral ligaments separately allow for their identification, later use in cuff repair, and, if desired, a McCall's culdoplasty at the end of the procedure. The cervix is then placed on outward and downward traction and the anterior vaginal tissue is elevated in the midline. Once the vesicouterine plane is fully developed, a lightweight right-angle retractor can be placed into the space to elevate the bladder and expose the anterior peritoneal fold. The anterior peritoneum is grasped and gently elevated and an anterior colpotomy performed with Metzenbaum scissors. Entry into the peritoneal cavity can be confirmed by seeing intraperitoneal fat. The incision opening is further stretched by spreading the scissors into the space to allow insertion of the right-angle retractor into the anterior cul-de-sac. This retractor should remain in position for the remainder of the hysterectomy to safely elevate the bladder out of the operative field. If a cystotomy occurs, the vaginal hysterectomy is usually completed before repair of the bladder.

The cervix is placed on outward and lateral traction, and the uterine artery is identified on one side and clamped with the curved Heaney clamp and cut. A suture of 0-gauge delayed absorbable sutures placed behind the clamp at the tip and is secured as the clamp is removed. The cervix is deflected to the opposite side and the opposite uterine artery is similarly ligated. The remainder of the broad ligament may be dissected with continued clamping and cutting on each side of the uterus. If the uterus a small and dissent is adequate, two curved Heaney clamps may be placed in tandem across the utero-ovarian ligaments, round ligament, and fallopian tubes. Each pedicle is double ligated. A simple suture on a passer is placed proximally and then with the transfixing stitch placed distally. Alternatively, if the uterus is large and dissent is poor, it may be brought closer to the surgeon and the vaginal introitus by using an alternate technique of intra-myometrial coring (Kovac, 1986). In this technique the myometrium can be circumferentially incised with the scalpel placed parallel to the long axis of the uterus and the serosal covering of the uterus with continuous traction on the cervix and direct visualization all times. This removes the core inside the uterus without violating the integrity of the endometrial cavity or uterine serosal. Plication of the uterine artery is necessary before coring. The coring incision reduces the size of the uterus by decreasing its width, by increasing its length. As the procedure continues, the uterus will begin to descend through the vagina, allowing the surgeon to visualize, clamp, and suture ligate the utero-ovarian ligament, round ligament, and fallopian tubes. An alternative technique is to bivalve the uterus with morcellation. A Lahey thyroid clamp may be placed on either side of the cervix, and with downward traction, the cervix may be incised with the scalpel vertically until the fundus of the uterus is reached. Once the fundus is reached, wedges of the myometrium are removed until the uterine size is significantly reduced to allow removal.

Once the pedicles are clamped and cut, the suture may be tagged and used to provide gentle traction on the pedicle and expose the ovary for evaluation or removal. Once the uterus has been removed, it is important to evaluate each pedicle to confirm hemostasis. At this point, either a salpingectomy and or oophorectomy may be performed if indicated. A uterosacral ligament suspension or McCall culdoplasty can be performed at this time also. The traditional McCall culdoplasty incorporates sutures in each uterosacral ligament accessed intraperitoneally and sutured to the posterior cuff (McCall, 1957). The McCall procedure begins by placing a moist pack into the posterior cul-de-sac; this helps prevent dissent of bowel or omentum into the operative field. The uterosacral ligaments, which were previously tagged during the vaginal hysterectomy, are placed on lateral tension to define the course of the ligament to the sacrum. The first suture row is placed caudad using 2-0 nonabsorbable monofilament suture. The first internal permanent suture is passed through the uterosacral ligament in a lateral-to-medial direction to avoid ureteral injury; subsequent series bites are placed 1 cm across the rectosigmoid serosa to reach and ligate the opposite uterosacral ligament. The sutures are left untied. Additional cephalad rows of sutures are similarly added with 1 cm between the rows being appropriate spacing. After completion of the 2 to 3 internal suture rows, one external suture is placed using 2-0 delayed absorbable monofilament suture that incorporates the posterior vaginal wall. The suture is initially placed through the full-thickness posterior vaginal wall and into the uterosacral ligament. Progressive bites are then taken serially through the rectosigmoid serosa to reach the opposite uterosacral ligament (Fig. 124.34A and B). Finally, the suture passed through the opposite uterosacral ligament and exits through the full thickness of the posterior vaginal wall to reenter the vagina. The sutures are then tied beginning with the most proximal suture and progressing caudad. Because of the proximity of the ureter to the uterosacral ligaments and placement of the sutures, cystoscopy should be performed to confirm ureteral patency. The vaginal cuff is then closed in either a vertical or transverse fashion with 2-0 delayed absorbable suture.

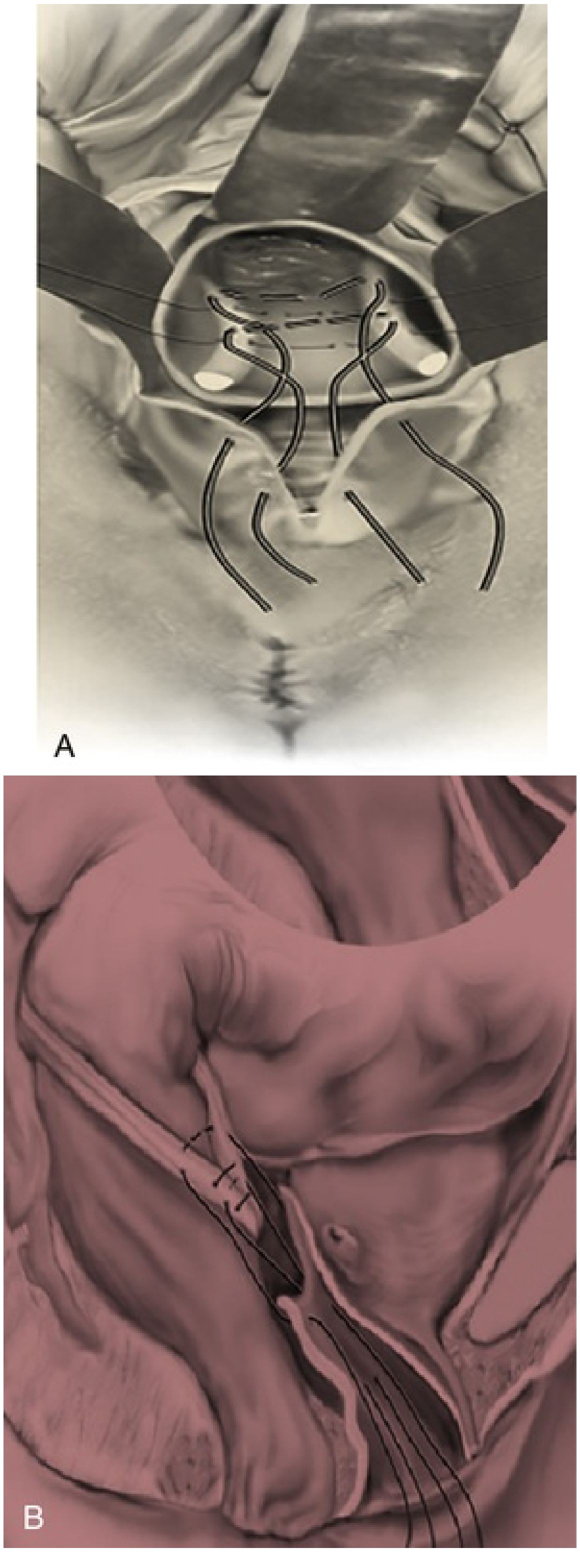

FIG. 124.34 (A and B) Internal and external McCall stitches are placed in a traditional fashion. Tying these sutures obliterates the cul-de-sac, supports the vaginal cuff, and increases posterior vaginal wall length. (From Walters M, Karram M: *Urogynecology and reconstructive pelvic surgery,* ed 4, Philadelphia, 2015, Saunders, p 366.)

Vaginal Hysterectomy Complications.

Intraoperative complications include visceral injury, intraoperative hemorrhage, and conversion of approach. Reported rates of hemorrhage range from 1.4% to 2.6% in vaginal hysterectomy (Harris, 1995; Weber and Lee, 1996). The incidence of urinary tract injury associated with hysterectomy for benign disease was 4.3%. The rate of bladder injury was 2.9%, and the rate of ureteral injury was 1.8% (Ibeanu et al., 2009). The rate of bowel injury was 0.4% (Dicker et al., 1982). A 0.4% conversion rate from vaginal to abdominal approach has been reported in a retrospective review of 220 patients (Kafy et al., 2006). In the Collaborative Review of Sterilization study of 1851 women undergoing elective hysterectomy for benign disease, 7.2% of patients experienced unexplained fevers with vaginal hysterectomy compared with 16.8% with abdominal hysterectomy. Urinary tract infections occurred in 3.4% of cases (Dicker et al., 1982). Other postoperative complications occured in less than 1% of patients and include vesicovaginal fistula, ileus, and fallopian tube prolapse (Harris, 1995). The incidence of vaginal vault prolapse after hysterectomy ranges from 0.2% to 43% (Barrington and Edwards, 2000; Cruikshank and Kovac, 1996; Toozs-Hobson et al., 1998).

A case-control study showed incidence of vaginal vault prolapse of 0.5% after hysterectomy (Dällenbach et al., 2008). Studies of hysterectomy outcomes indicated that symptom levels in women undergoing hysterectomy are generally high and have a substantial impact on quality of life. Their symptoms before surgery are noted to be significantly improved after the procedure (Kulkarni and Rogers, 2010). Significant improvement in mood states such as depression, anxiety, and irritability have been consistently reported (Carlson et al., 1994; Sculpher et al., 1996). Disruption of local nerve and supportive structures along with the changes in anatomic relationship the pelvic organs may result in altered sexual function. Few studies have attributed the decline in sexual function to hysterectomy (Kilkku, 1983). Studies have concluded that sexual function either improved or remained unchanged for the majority of women after hysterectomy, with or without cervical preservation. This study of 187 women examining the effects of different types of hysterectomy on sexual function prospectively noted that the percentages of patients reporting symptom improvement for the vaginal hysterectomy group were as follows: coital frequency 44.3%, deep dyspareunia 19.7%, libido 19.7%, achievement of orgasm 32.8%, and overall satisfaction

28.3% (El-Toukhy et al., 2004). The positive impact of surgery on sexual function was observed for total abdominal hysterectomy as well as laparoscopic hysterectomy and same study (El-Toukhy et al., 2004).

Uterine Sparing and Hysteropexy

Traditionally, surgical repairs to restore pelvic floor support in the setting of uterine prolapse included hysterectomy. Recently, however, there has been great interest in preservation of the uterus in prolapse surgery, to maintain future fertility, decrease surgical risk associated with the hysterectomy, and to satisfy women who feel a sense of identity with maintaining their uterus and who feel concerned about sexual function with the loss of their uterus (Maher et al., 2013).

Hysteropexy may be performed either by vaginal or abdominal approaches, although most abdominal approaches are being performed either laparoscopic or robotically. Frick et al. (2013) found that 60% of women surveyed indicated they would decline hysterectomy if presented with an equally efficacious alternative to a hysterectomy-based prolapse repair. In another study, Korbly et al. (2013) found that 36% of women preferred uterine preservation when presented with equally efficacious surgical options; 21% of women in this study continued to prefer uterine preservation, even when the uterine-sparing prolapse procedure was associated with worse efficacy. It is generally accepted that the uterus plays a passive role in the development of prolapse (DeLancey, 1992). The need for hysterectomy at the time of prolapse repair has never been proven. **Therefore hysterectomy may not be necessary to correct the underlying defect in the apical vaginal support structures of the uterosacral/cardinal ligament complex** (Bradley et al., 2018). **Uterine preservation is considered safe in select groups of women but is contraindicated in those with abnormal uterine or cervical pathology and certain medical histories** (Table 124.13; Ridgeway, 2015). Uterine-sparing procedures have been shown to decrease operative time and estimated blood loss (Ridgeway, 2015). There are no published RCTs comparing efficacy and/or safety between hysteropexy procedures to recommend one approach over another. There is, however, high-quality evidence comparing similar types of prolapse repairs with and without hysterectomy (Bradley et al., 2018). See Table 124.14 for perceived and studied advantages and disadvantages of uterine-preservation at the time of prolapse surgery

TABLE 124.13

Contraindications for Uterine Preservation

Postmenopausal bleeding
Current or recent cervical dysplasia
Familial cancer syndrome, *BRCA1* and *BRCA2*
Hereditary nonpolyposis colonic cancer syndrome
Tamoxifen therapy
Uterine abnormalities
Fibroids, adenomyosis, abnormal endometrial sampling
Abnormal uterine bleeding
Inability to comply with routine gynecologic surveillance
Cervical elongation (relative contraindication)

Modified from Ridgeway: Uterine conservation for pelvic organ prolapse. *Am J Obstet Gynecol* 2015.

TABLE 124.14

Perceived and Studied Advantages and Disadvantages of Uterine Preservation at the Time of Prolapse Surgery

ADVANTAGES	DISADVANTAGES
Reduction in surgical time and blood loss Maintenance of fertility Natural menopausal timing Avoidance of an unnecessary procedure Perceived role of the uterus and cervix in pelvic stability and sexual satisfaction Less invasive Association with quicker recovery Decreased risk of mesh exposure Similar short-term outcomes Patient preference	Fewer surgical outcome data available Maintenance of fertility Small, ongoing risk for cervical or endometrial cancer Subsequent hysterectomy may be difficult Continuation of menses Ongoing surveillance of cervix and endometrium Colpopexy may be easier for surgeon after hysterectomy

Modified from Ridgeway BM, Frick AC: Uterine conservation for the surgical treatment of uterovaginal prolapse. In Karram M, Walters M, editors: *Urogynecology and reconstructive pelvic surgery*, 4th ed, Philadelphia, 2015, Elsevier Saunders, pp. 383–399.

Transvaginal Uterine-Sparing Techniques.

Transvaginal approaches to uterine-sparing procedures may be performed with and without mesh. There are four techniques described for uterine-sparing transvaginal surgeries: the Manchester operation, uterosacral ligament fixation, sacrospinous ligament fixation, and LeFort colpocleisis (see section on colpocleisis for details).

Manchester Procedure.

The Manchester procedure was first described in 1888 by Archibald Donald of Manchester, England, for the treatment of cervical elongation. Procedure involves amputation of the cervix, cardinal and uterosacral ligament plication, and anterior and posterior colporrhaphy (Tola et al., 2015). Fothergill modified the technique, giving the anterior colporrhaphy incision a triangular shape with its base near the cervix and plicating the parametrium anterior to the cervix (Pearce, 2004). The operation has been known as the Manchester Donald Fothergill operation.

Once anesthesia is adequate, the patient is prepped and draped in the usual sterile fashion and placed in dorsal lithotomy position in stirrups. A Foley catheter is inserted into the bladder. A Lone Star self-retaining retractor can be used to facilitate exposure. A Lahey-thyroid clamp is placed on the anterior and posterior lip of the cervix, and the cervix is placed on traction in an outward direction. A circumferential incision is made around the cervix, dissecting the vaginal epithelium similar to the first steps of a vaginal hysterectomy, and clamping and transecting the uterosacral/cardinal ligaments bilaterally. The elongated cervix is amputated, the remaining cervix is retracted downward, and the uterosacral/cardinal ligament pedicles are sutured to the anterior aspect of the remaining cervix. This fixation may be performed with either delayed absorbable or permanent suture. A 5-mm Hegar dilator can be inserted into the cervical canal to help identify it. The cervical stump is then covered with the vaginal epithelium, leaving the uterine canal open. Additional surgical procedures, such as anterior or posterior repair or anti-incontinence procedures, can then be performed if indicated. Cystoscopy is performed to confirm ureteral patency.

Manchester Procedure Complications.

Complications related to the Manchester procedure must be taken in context of when the procedures were performed. In the series describing 960 patients, the procedures were performed from 1936 to 1955 and reported the following complications: cystotomy and proctotomy less than 0.5%, blood transfusion

20%, febrile morbidity 63%, urinary retention 15.2%, and mortality 0.7% (Ridgeway and Frick, 2015). The Ayhan et al. (2006) study reported the following complication rate in 232 patients undergoing the Manchester procedure from 1985 to 2004: early postoperative complications; 13.23% had febrile morbidity; retroperitoneal hematoma occurred in 0.49%; urinary retention occurred in 22.05%, and cervical stenosis 11.27%. At 1 year, 1 patient had undergone abdominal hysterectomy because of unsuccessful cervical dilation. At a mean of 3.6 years after the operation, 3.9% had undergone the tension-free vaginal tape procedure plus a vaginal hysterectomy for recurrent SUI and uterine prolapse. Tipton and Atkin (1970) examined 82 premenopausal women 6 to 12 years after they underwent the Manchester operation and found that uterine carcinoma had developed in 2.4%. Hopkins et al. (1997) also reported on 2 patients in whom adenocarcinoma of the endometrium developed in the retained uterus after they underwent the Manchester operation. This procedure is also associated with obstetric complications such as subfertility, infertility, prolonged labor, and pregnancy loss (Tola et al., 2015).

Manchester Procedure Results.

See Table 124.15 for a summary of studies. A retrospective study by Thomas et al. (1995) reported an anatomic cure rate of 94% in 88 patients. The authors concluded that the Manchester operation is quick, efficacious, and associated with less blood loss than vaginal hysterectomy. In the study by Tipton and Atkin (1970), the reoperation rate among 82 women treated with the Manchester operation for uterine prolapse 6 to 12 years after initial surgery was 21% because of recurrence, bleeding, or cancer. Comparisons of the Manchester operation with vaginal hysterectomy have often overlooked the fact that there are more vault prolapses after vaginal hysterectomy, whereas cystoceles recur more often after Manchester operations (Pearce, 2004; Thomas et al., 1995). Conger and Keettel in 1958 and Thomas et al. in 1995 reported the rates of recurrent prolapse to be approximately 4.3% and 6.0%, respectively. Ayhan et al. (2006) echoed a similar rate with recurrent prolapse rate of 3.9% for uterine prolapse and 1.47% for cystocele or rectocele in 204 patients.

TABLE 124.15

Vaginal Approach to Hysteropexy

	DURATION	OBJECTIVE

STUDY	PROCEDURE	# OF PATIENTS	OF FOLLOW-UP, MO	SUCCESS RATE WITH DEFINITION (%)	SU SU R

Modified from Ridgeway BM, Frick AC: Uterine conservation for the surgical treatment of uterovaginal prolapse. In Karram M, Walters M, editors: *Urogynecology and reconstructive pelvic surgery*, 4th ed, Philadelphia, 2015, Elsevier Saunders, pp. 383–399.

Transvaginal Uterosacral Ligament Hysteropexy Technique.

Once anesthesia is adequate, the patient is prepped and draped in the usual sterile fashion and placed in dorsal lithotomy position in stirrups. A Foley catheter is inserted into the bladder. A Lone Star self-retaining retractor can be used to facilitate exposure. A Lahey-thyroid clamp is placed on the posterior lip of the cervix, and the cervix is placed on traction in an outward and upward direction. A posterior colpotomy is performed to gain entry into the posterior peritoneal space. The bowel is packed out of the operative field with a moist laparotomy sponge to allow identification of uterosacral ligaments on each side. Gentle traction with an Allis clamp is exerted on the caudal part of the ligament, and two to three transfixion sutures of monofilament 0-gauge delayed absorbable or permanent suture are placed through the ligament bilaterally. The lowest suture is placed at the level of the ischial spine, and the two following are placed 1 cm above each. In total, four to six sutures are positioned.

To minimize ureteral injury risk, sutures are passed in a lateral to medial direction. After suture placement, the vaginal pack is removed. Each anterior needle is passed posteriorly through the peritoneum and full thickness of the vaginal epithelium. Each posterior needle is passed anteriorly through the peritoneum, pericervical ring, and vaginal epithelium. If permanent suture is used, it is important that the suture not pass through the vaginal epithelium, and the sutures should be tied within the abdominal cavity and not in the vaginal lumen. The most distal uterosacral ligament sutures were passed laterally, the proximal ones medially, and the intermediate ones between the previous sutures. Digital splinting of the prolapsed uterus into normal position at the vaginal apex is followed by counter-traction on the uterosacral suspension sutures, removing all slack to the maximum resuspension. All sutures were tied to close the cul-de-sac and the posterior vaginal colpotomy incision. Additional surgical procedures, such as anterior or posterior repair or anti-incontinence procedures, can then be performed if indicated. Cystoscopy is then done to confirm ureteral patency.

Transvaginal Uterosacral Ligament Hysteropexy Complications.

Williams (1966) reported a complication rate of 20%. Complications of the uterosacral ligament suspension included genital urinary tract infections, cellulitis, and atonic bladder symptoms. In a Romanzis 2012 study, the complication rate was 6% (Rideway and Frick, 2014). Operative data showed a 15% complication rate, with none directly related to uterine preservation. Recurrences were noted in 25% of patients, but 40% of them were due to cervical elongation. Cervical elongation can occur after hysteropexy in up to 62% of patients (Hyakutake et al., 2014; Kapoor et al., 2017; Rosen et al., 2008). In the Williams transvaginal uterosacral plication method, ureteral injury and neurologic morbidity are high in this type because the uterosacral ligaments are divided then plicated in the midline, and ureteral dissection cannot be adequately performed (Price et al., 2010). Another disadvantage of this method is that the plication portion is low because the uterosacral ligaments are transected close to the uterus (Tola et al., 2015).

Transvaginal Uterosacral Ligament Hysteropexy Results.

See Table 124.15 for a summary of studies. There are no RCTs that compare uterosacral hysteropexy to any other type of prolapse repair (uterine-sparing or hysterectomy based) nor is there any study comparing different approaches to uterosacral hysteropexy (transvaginal vs. minimally invasive) (Ridgeway and Cadish, 2017). In the 1966 case series by Williams it was reported that women who had uterovaginal prolapse at least to the introitus had a failure rate of 15%. In a large retrospective 2012 study comparing 100 women who underwent total vaginal hysterectomy with uterosacral ligament suspension with 100 women who underwent transvaginal uterine sparing uterosacral ligament suspension, there was no difference in outcomes at 24 months (Romanzi and Tyagi, 2012). In this same series the hysteropexy group apical success was noted to be 96%, anterior wall success was noted to be 86.8%, and posterior wall success was noted to be 97.8%, all of which were statistically similar to the hysterectomy group. There are conflicting data and a lack of RCTs comparing success rates of hysteropexy versus hysterectomy with uterosacral ligament suspension. Studies use different approaches to uterosacral ligament suspension, which may also account for these differences (Bradley et al., 2018).

Sacrospinous Hysteropexy Technique.

The patient is placed in lithotomy position, and an indwelling catheter is inserted. Adequate exposure is used to inspect the posterior vaginal wall and mark the proximal extent of the incision to prevent compromise of the apical tissue that will be used for vaginal vault fixation. A posterior vaginal wall incision is made deep to the rectovaginal fascia. If the patient has significant posterior compartment prolapse and a posterior repair is planned, then the incision should be made superficial to the rectovaginal fascia. The right-sided pararectal space is entered bluntly, the ischial spine is palpated, and tissue overlying the sacrospinous ligament is swept lateral to medial until the sacrospinous ligament is exposed. Two permanent or delayed absorbable sutures are placed through the sacrospinous ligament, either under direct vision by free suturing, with the aid of reusable ligature carriers such as the Miyazaki hook or the Deschamps needle ligature carrier or the Capio Suture Capturing Device (Boston Scientific, Marlborough, MA), taking care to avoid placement too close to the ischial spine. The posterior cervix is exposed, and a free needle is used to pass the two sutures through the posterior cervix, after which the posterior fornix is examined to ensure that the sutures are not protruding through the vaginal wall. The posterior vaginal incision is then closed. The surgeon ties down the two sacrospinous sutures to ensure tissue apposition, being sure to bury the knots under the vaginal mucosa if permanent suture is used. If indicated, anterior and/or anti-incontinence procedure can be performed. Cystoscopy is performed to confirm ureteral patency.

Sacrospinous Hysteropexy Complications.

Complications related to sacrospinous hysteropexy include rates of excessive blood loss ranging from 1.4% to 8%, rectal injury at 0.8%, urinary tract infection rates between 10% and 30%, urinary retention in 27%, and buttock pain in 10% to 15% (Dietz et al., 2008; van Brummen et al., 2003). Buttock pain typically resolves within 6 weeks; however, if a patient has specific neurologic symptoms and severe buttock pain, this likely represents sacral plexus or pudendal nerve entrapment and requires suture removal. Dietz et al. (2008) in a prospective study supported these findings and reported the following complications: reoperation for hemorrhage 1.4%, vaginal hematoma 2.8%, vaginal adhesion 4.2%, urinary tract infection 9.7%, buttock pain 18.1%, and urinary retention 27.8%. Additional studies report an ureteric obstruction rate of 2.9% (Beer and Kuhn, 2005; Sylvester et al., 2012). This complication profile seems acceptable compared with other treatment options for uterovaginal prolapse (Ridgeway and Frick, 2015).

Sacrospinous Hysteropexy Results.

See Table 124.15 for a summary of studies. **The sacrospinous hysteropexy is the best-studied uterine-sparing procedure** (Tola et al., 2015). **The literature contains numerous data points, as well as functional, reproductive, and sexual outcomes. Results of this procedure were first presented in 1998 in a case series. Five patients ranging in age from 24 to 31 were followed for 6 to 24 months.** No recurrences of prolapse nor pregnancy was reported. However, the data lack description of perioperative prolapse and definitions of success (Richardson et al., 1989). A larger study by Dietz et al. (2007) describes 133 women who underwent unilateral sacrospinous hysteropexy and anterior/posterior colporrhaphy as indicated. In this study 99 women responded to email questionnaires and 60 followed up for detailed POP-Q examination. At a mean follow-up of 22.8 months, 6% of the 133 women were diagnosed with recurrent uterovaginal prolapse to at least 1 cm above the hymen, 30% had stage 2 anterior vaginal wall prolapse, and 8% had stage 3 anterior vaginal wall prolapse. Of all patients, only three (2.8%) women required surgical treatment for recurrent prolapse. The majority of patients were very satisfied with the results of the surgery, and 91% would recommend the procedure to other women. In a large randomized trial Detollenaere et al. (2015) found sacrospinous hysteropexy to be not inferior to vaginal hysterectomy with uterosacral ligament suspension.

The primary outcome for the study was symptomatic recurrent apical prolapse at 12 months. There was no significant difference between the groups. A high rate of anatomic failure in both groups was noted in the anterior compartment (47% vs. 33%, RD 12.5; 95% CI 0.5–26.4). There was no statistically significant difference in overall anatomic and functional outcomes, complications, hospital stay, and sexual function (Detollenaere et al., 2015). Five-year follow-up is planned and should provide valuable insight to long-term outcomes (Kapoor et al., 2017). In another randomized trial, Dietz et al. (2010) compared sacrospinous hysteropexy with transvaginal hysterectomy and uterosacral ligament suspension in 71 women with the primary outcome of return to activities at home and work. At 1 year, 27% of women who underwent hysteropexy had recurrent prolapse (stage 2 or greater) compared with 11% after hysterectomy and uterosacral ligament suspension. Reoperation rates were similar. There was no difference in validated questionnaires for prolapse symptoms, incontinence symptoms, and QoL (Dietz et al., 2010).

Maher et al. (2001) reported on 77 women with uterovaginal prolapse to at least the introitus that self-selected to hysterectomy with sacrospinous ligament fixation or sacrospinous hysteropexy. Although not randomized, the groups were similar in all categories. The operative time and intraoperative blood loss were significantly less for the hysteropexy group. Fifty-six patients were available for follow-up; all were evaluated by a nonsurgical member who was blinded to the treatment with a mean follow-up of 33 months for the hysterectomy group and 26 months for the hysteropexy group. The subjective success rate was 86% in the hysterectomy group and 78% in the hysteropexy group. The objective cure rate (no prolapse beyond the mid-vagina) was similar between groups, 72% and 74%, respectively. Only two patients became pregnant in this cohort, delivering by cesarean section, with one requiring additional surgery for prolapse postdelivery (Maher et al., 2001).

van Brummen et al. (2003) mailed 103 questionnaires to women who underwent either vaginal hysterectomy or sacrospinous hysteropexy and possible anterior and posterior colporrhaphy for prolapse greater than or equal to grade II on the Baden-Walker system. The recurrence rate of grade 2 or higher vaginal prolapse was 11.4% for the sacrospinous hysteropexy group and 6.7% for the vaginal hysterectomy groups, which was not statistically significant (van Brummen et al., 2003).

Sacrospinous hysteropexy is usually done unilaterally. This deviates the axis of the vagina to the right; as a result dyspareunia and sexual function are concerns. A study by Lin et al. (2005) with a follow-up of at least 5 years noted that cervical elongation ($P = 0.007$) and grade 3 uterine prolapse are significant risk factors for failure after sacrospinous hysteropexy. The authors modified their technique based on these findings and reported that concomitant partial trachelectomy for patients with cervical elongation significantly reduced the failure rate from 75% to 0 ($P = 0.024$). Jeng et al. (2005) evaluated 150 women, all were younger than 50 years old and sexually active within the last 6 months before surgical intervention. Sexual functioning before and 6 months after surgery was examined via a face-to-face questionnaire. Sexual interest, sexual satisfaction, frequency of sexual intercourse, and frequency of orgasm were measured using an analog scale. Frequency of orgasm was the only parameter that changed significantly after surgery in the 2 groups. The sexual functioning scores were not different before or after surgical intervention in either group (Jeng et al., 2005).

Minimally Invasive Uterosacral Hysteropexy Technique.

Uterosacral ligament suspension can be performed in a minimally invasive technique using laparoscopy or with the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA). Although there are minute variations between the two different approaches of minimally invasive uterosacral uterine suspension, each procedure attaches the uterus to a more proximal portion of the uterosacral ligament. The patient can be placed on a Pink Pad (Xodus Medical, New Kensington, PA) or another device to prevent slippage. After administration of general anesthesia, the patient is properly positioned in Allen stirrups in a low lithotomy position, the arms are properly tucked to the side and all bony prominences are padded, a pelvic exam is performed, the abdomen and vagina are surgically prepared, and a Foley catheter is inserted into the bladder. A uterine manipulator such as the Rumi II Koh System/Advincula Arch Koh System (CooperSurgical, Trumbull, CT), Vcare Plus (ComMed, Utica, NY), or another can be inserted.

Trocar placement begins with entry into the abdominal cavity via the technique with which the surgeon is most experienced. The abdomen is inflated with CO_2 gas once entry into the abdomen is confirmed. A 0-degree laparoscope is inserted through the umbilical trocar and careful inspection of the peritoneal cavity is performed, delineating all the pertinent anatomy to performing the uterosacral ligament suspension. Depending on the anatomy and whether adhesiolysis is necessary, additional trocar placement can be performed. There are many variations of trocar placement described, but in general, trocar placement involves two additional trocars placed under direct visualization in the right and left lower quadrants, lateral to the inferior epigastric vessels. One or two additional 5-mm ports are placed at the level of the umbilicus, lateral to the rectus muscle. Additional 5-mm trocar ports can be placed on the principal surgeon's side so that he or she can operate with two hands. With use of the da Vinci Surgical System, a 8.5-mm robotic camera trocar is placed at the umbilicus, and two to three additional 8.5-mm robotic trocars are placed at least 9 cm apart in either a semi-lunar or W configuration. An additional 8.5- to 11-mm laparoscopic trocar is placed on the right side of the patient to allow for the surgical assistant access. The bed is moved into the Trendelenburg position, and side or parallel docking is preferred to allow access to the vagina, bladder, and rectum intraoperatively. The pelvis is inspected, the bowel is swept out of the pelvis, and both uterosacral ligaments and ureters are identified. The proximal sacral portion of each ligament is grasped and put on tension. If the ureter is in close proximity to the uterosacral ligament, a peritoneal release incision can be performed to reduce ureteral kinking. A 0-gauge nonabsorbable or monofilament delayed absorbable suture is passed through the sacral and midportion of the ligament in 2 bites, securing it to the insertion portion of the ligament at the cervix. Additional sutures may be placed at the surgeon's discretion. The steps are repeat on the contralateral side. The uterine manipulator is directed toward the sacrum and the sutures are tied. Cystoscopy is performed to confirm ureteral patency. Any additional indicated procedures are then performed.

Minimally Invasive Uterosacral Hysteropexy Complications.

The existing literature indicates that laparoscopic uterosacral ligament uterine suspension is safe. When compared with vaginal hysterectomy with vault suspension, laparoscopic uterosacral ligament suspension resulted in less blood loss ($P < 0.0001$) and a shorter hospital stay ($P < 0.002$) (Diwan et al., 2006). In this retrospective cohort the mean reported operating time was less than an hour. Complications reported were few and included a uterine artery laceration resulting in a broad ligament hematoma that required laparotomy and transfusion and two cases involving ureteral linking remedied by a peritoneal ureteral-releasing incision.

Minimally Invasive Uterosacral Hysteropexy Results.

See Table 124.16 for a summary of studies. There are no RCTs comparing laparoscopic to robotic uterosacral uterine suspension, and most of the available data on outcomes come from studies retrospective studies comparing laparoscopic uterosacral uterine suspension to vaginal hysterectomy with uterosacral suspension. The current data available suggest that laparoscopic ligament hysteropexy is relatively safe and effective. A prospective study by Maher et al. (2001) reported outcomes on 43 nonobese patients with predominate anterior or uterine prolapse to or beyond the vaginal introitus undergoing laparoscopic uterosacral ligament uterine suspension and concomitant repairs deemed necessary. At a mean follow-up of 12 months, 81% of patients had no prolapse symptoms and 79% had no evidence of uterine prolapse recurrence; 16% (7/43) of patients had repeat surgery for recurrent prolapse (Maher et al., 2001). Recently, a retrospective cohort by Haj Yahya et al. (2017) echoed similar results in a series in which 48 women underwent laparoscopic uterosacral ligament uterine suspension with an anatomic cure rate of 85.4% (no prolapse at or below 1 cm above the hymen). The mean follow-up was 17.5 months and a clinical cure rate of 95.8%. One patient needed a repeat surgery for recurrent uterine prolapse 3 years postoperatively. They also reported no intraoperative complications such as blood loss requiring transfusion, bowel injury, or ureteral kinking. In this same series 95.5% of subjects reported their condition as very much better (PGI-I-A) or much better (PGI-I-B) (Haj Yahya et al., 2017).

TVH, Total vaginal hysterectomy.

Diwan et al. (2006) were the first to compare laparoscopic uterosacral ligament uterine hysteropexy to vaginal hysterectomy with vaginal vault suspension in a retrospective cohort of 50 patients. The authors concluded that the uterine suspension procedure is a safe, effective treatment in selected patients with uterovaginal prolapse (Diwan et al., 2006). In another retrospective study, Turner et al. (2016) compared 54 patients who underwent uterosacral uterine suspension with 119 patients who underwent vaginal uterosacral ligament suspension. In the uterosacral uterine suspension group, a 13.2% recurrence rate was noted with no statistically significant difference when compared with the vaginal uterosacral ligament suspension group (Turner et al., 2016). Nair et al. (2017) recently published a systematic review on the anatomic and functional outcomes in women undergoing laparoscopic hysteropexy. A total of 770 patients in 17 studies were included in the review. Laparoscopic suture hysteropexy pooled success rate was 70.5%. The authors concluded that laparoscopic hysteropexy was associated with good anatomic cure rates of greater than 90% in most of the studies. There was an improvement in symptoms, and subjective cure rates were good in 73% to 100% of the patients. Reoperation rates were low, ranging from around 0 to 28%, and complication rates were generally low (Nair et al., 2017).

Open Abdominal Sacrohysteropexy Technique.

After administration of general anesthesia, the patient is properly positioned in Allen stirrups in a low lithotomy position, the arms are properly tucked to the side, and all bony prominences are padded, a pelvic exam is performed, the abdomen and vagina are surgically prepared, and a Foley catheter is inserted into the bladder. A uterine manipulator may be inserted into the uterus such as the Hulka-Kenwick Uterine elevating and manipulating forceps (Novo Surgical, Oak Brook, IL). Using a uterine manipulator such as this allows for additional instruments to be inserted into the vagina to delineate the vagina and posterior fornix. Alternatively, a RUMI uterine manipulator with a KOH colpotomizer system (CooperSurgical, Trumbull, CT) can be used. The use of a uterine manipulator allows the assistant to push up the vaginal wall, and the posterior fornix and dissection of the vesicovaginal and rectovaginal space can be done without difficulty. A Pfannenstiel or low midline abdominal incision may be used.

Upon surgical entry into the peritoneal cavity, it is important to achieve exposure of the true pelvis by careful packing of the small intestine and sigmoid colon. This is accomplished by releasing all adhesions in the pelvis and packing the bowel above the level of the sacral promontory and displacing the sigmoid to the left, exposing the sacral promontory and posterior peritoneum. To begin, the bladder is mobilized from the cervix to expose 3 to 4 cm of the underlying pubocervical fascia and proximal vagina. Bilateral windows are then made in the broad ligament at the level of the cervicouterine junction lateral to the uterine artery in an avascular area. Posteriorly, the rectovaginal space is entered at the level of the uterosacral ligaments and developed using blunt dissection to expose the rectovaginal fascia. The peritoneum overlying the sacral promontory is elevated and incised until the anterior longitudinal ligament is identified. Careful dissection is used to avoid the injury to middle sacral vessels. The peritoneum from the promontory is then incised along the right pelvic side wall to the posterior apex of the vagina. The course of the right ureter should be noted before creation of the peritoneal leaflets. A self-styled Y-shaped, T-shaped or oval-shaped-with-arms piece of monofilament polypropylene large-pore mesh can be used for the anterior vagina and cervix. The left and right mesh arms are passed through the left and right broad ligament and attached to the cervix and upper vagina with 2-0 polydioxanone sutures or monofilament, nonabsorbable polypropylene suture. If a Y-shaped mesh is not used, a rectangular second piece of monofilament polypropylene large-pore mesh is fixated to the posterior vagina and cervix with 2-0 polydioxanone sutures or monofilament, nonabsorbable polypropylene suture. The assistant then elevates the vagina and uterus toward the sacral promontory. The anterior long arms of the mesh and the posterior graft are fixed to the sacral promontory using 2 to 3 nonabsorbable monofilament sutures. Finally, the peritoneum is reapproximated. Cystoscopy is performed to confirm ureteral patency. Any additional indicated procedures are then performed.

Minimally Invasive Sacrohysteropexy Technique.

Sacrohysteropexy can be performed in a minimally invasive technique using laparoscopy or with the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA). However, there are few variations with the two different approaches of minimally invasive sacrohysteropexy. The patient can be placed on a Pink Pad (Xodus Medical, New Kensington, PA) or another device to prevent slippage. After administration of general anesthesia, the patient is properly positioned in Allen stirrups in a low lithotomy position, the arms are properly tucked to the side, and all bony prominences are padded, a pelvic exam is performed, the abdomen and vagina are surgically prepared, and a Foley catheter is inserted into the bladder. A uterine manipulator may be inserted into the uterus such as the Hulka-Kenwick uterine elevating and manipulating forceps (Novo Surgical, Oak Brook, IL). Using a uterine manipulator such as this allows for additional instruments to be inserted into the vagina to delineate the vagina and posterior fornix. Alternatively, a RUMI uterine manipulator with a KOH colpotomizer system (CooperSurgical, Trumbull, CT) can be used. The use of a uterine manipulator allows the assistant to push up the vaginal wall and the posterior fornix, and dissection of the vesicovaginal and rectovaginal space can be done without difficulty.

Trocar placement begins with entry into the abdominal cavity via the technique with which the surgeon is most experienced. The abdomen is inflated with CO_2 gas once entry into the abdomen is confirmed. A 0-degree laparoscope is inserted through the umbilical trocar, and careful inspection of the peritoneal cavity is performed, delineating all the pertinent anatomy to perform the sacrohysteropexy. Depending on the anatomy and whether adhesiolysis is necessary, additional trocar placement can be performed. There are many variations of trocar placement described when performing robotic and laparoscopic approaches, but, in general, trocar placement involves two additional trocars placed under direct visualization in the right and left lower quadrants, lateral to the inferior epigastric vessels. One or two additional 5-mm ports are placed at the level of the umbilicus, lateral to the rectus muscle. Additional 5-mm trocar ports can be placed on the principal surgeon's side so that he or she can operate with two hands.

With use of the da Vinci Surgical System, a 8.5-mm robotic camera trocar is placed at the umbilicus, and two to three additional 8.5-mm robotic trocars are placed at least 9 cm apart in either a semi-lunar or W configuration. An additional 8.5- to 11-mm laparoscopic trocar is placed on the right side of the patient to allow for the surgical assistant access. The bed is moved into the Trendelenburg position, and side or parallel docking is preferred to allow access to the vagina, bladder, and rectum intraoperatively. If performed laparoscopically, a 30-degree laparoscope is used. To begin, the bladder is mobilized from the cervix to expose 3 to 4 cm of the underlying pubocervical fascia and proximal vagina. Bilateral windows were then made in the broad ligament at the level of the cervicouterine junction lateral to the uterine artery in a vascular area. Posteriorly, the rectovaginal space was entered at the level of the uterosacral ligaments and developed using blunt dissection to expose the rectovaginal fascia, this dissection can be continued to the perineal body if indicated. The peritoneum overlying the sacral promontory is elevated and incised until the anterior longitudinal ligament is identified. Careful dissection is used to avoid the injury to middle sacral vessels. The peritoneum from the promontory is then incised along the right pelvic side wall to the posterior apex of the vagina.

The course of the right ureter should be noted before creation of the peritoneal leaflets that will be used to cover the graft. A self-styled Y-shaped, T-shaped, or oval-shaped-with-arms piece of monofilament polypropylene large-pore mesh can be used for the anterior vagina and cervix. The left and right mesh arms are passed through the left and right broad ligament and attached to the cervix and upper vagina with 2-0 polydioxanone sutures or monofilament, nonabsorbable polypropylene suture. If a Y-shaped mesh is not used, a rectangular second piece of monofilament polypropylene large-pore mesh is fixated to the posterior vagina and cervix with 2-0 polydioxanone sutures or monofilament, nonabsorbable polypropylene suture. The posterior mesh should be fixated along the entire area of the rectovaginal dissection. A 30-degree angled camera scope improves visualization at this portion of the procedure. Care is taken to avoid the uterine vessels when placing the needle into the posterior aspect of the cervix and to avoid the ureters (especially the right ureter) during the procedure. The assistant then elevates the vagina and uterus towards the sacral promontory. The anterior long arms of the mesh and the posterior graft are fixed to the sacral promontory using 2 to 3 nonabsorbable polypropylene sutures (Ethicon Endo-surgery sutures). Finally, the peritoneum is reapproximated with poliglecaprone 25 or Vicryl suture. Cystoscopy is performed to confirm ureteral patency. Any additional indicated procedures are then performed.

Minimally Invasive Sacrohysteropexy Complications.

Although minimally invasive sacrohysteropexy may result in less blood loss, shorter hospital stays, decreased operative time, and avoidance of hysterectomy-specific complications, it can complicate future hysterectomy should it become necessary. It appears that complications of sacrohysteropexy are similar to those of sacrocolpopexy. Reported complications include wound infection, small bowel obstruction, hernia, mesh exposure, de novo incontinence, urinary urgency, dyspareunia, and persistent pain (Ridgeway, 2015). Mesh erosion is estimated at 4.2% within the first 12 months of surgery (Grimminck et al., 2016; Siddiqui et al., 2015). New-onset dyspareunia has been reported in 7% to 15% of subjects (Ridgeway, 2015). In one study with a 4-year follow-up, the mesh exposure rate was 3% (Barranger et al., 2003).

Sacrohysteropexy Results.

See Table 124.17 for a summary of studies. **The evidence supporting sacrohysteropexy is more robust compared with other open abdominal uterine conservation procedures** (Ridgeway, 2015). Most studies are limited by small sample size and lack of comparison groups. In a prospective study by Moiety et al. (2010), 33 women with a mean age of 45 (29–65) underwent open abdominal sacrohysteropexy. Preoperative POP-Q stage 2 was noted in 27 patients and stage 3 in 6 patients. At a relative short follow-up of 6 months, only 2 cases showed recurrence, and the objective and subjective success rates were 93.93% and 81.8%, respectively (Moiety et al., 2010). A retrospective cohort of 30 patients by Barranger et al. (2003) reported high objective and subjective success rates. The mean age of the women was 35.7 years (range, 29–43 years). All women were parous, 13 women had grade 2 uterovaginal prolapse, and 17 women had grade 3 prolapse. In addition to sacrohysteropexy all women underwent the Burch procedure and posterior colporrhaphy. Intraoperative and postoperative complications occurred in 2 patients (6.6%) and 4 patients (13.3%), respectively. The mean objective and subjective follow-up periods were 44.5 months (range, 2–156 months) and 94.6 months (range, 8–160 months), respectively; 93% of patients had no prolapse beyond the hymen at a mean follow-up of 44.5 months. Subjective rates were high as well; only 1 patient experienced recurrent prolapse symptoms at a mean follow-up of 95 months (Barranger et al., 2003).

Grimminck et al., 2016	Prospective	100	Robotic-assisted sacrohysteropexy	None	12 and 7 months

Limited data exist on the outcomes and complications of minimally invasive sacrohysteropexy. Published studies on the outcomes of laparoscopic sacrohysteropexy and robotic-assisted laparoscopic sacrohysteropexy are similar and seen as an effective alternative to the open approach (Paek et al., 2016). Lack of data on midterm and long-term follow-up have so far prevented the standard treatment for POP. There is no consensus on which technique would be most preferable; furthermore that is the question of whether uterine preservation is favorable (Grimminck et al., 2016). No RCTs have been published comparing sacrohysteropexy with hysterectomy with sacrocolpopexy. Costantini et al. (2005) reported a 91% success rate with abdominal sacrohysteropexy (*n* = 34) versus 92% with abdominal hysterectomy and sacrocolpopexy (*n* = 38) at 51 months. In 2013 Constantini et al. followed 32 sacrohysteropexy patients for 12 months with 100% objective success in both groups (apex <−6). Krause et al. (2006) followed 81 women prospectively after laparoscopic sacral suture hysteropexy (attaches the posterior cervix to the sacral promontory via the right uterosacral ligament). At a mean follow-up of 20.3 months, 88% had no symptoms of POP, whereas 95% had no objective evidence of prolapse (Krause et al., 2006). Data by Rosenblatt et al. (2008) on 23 women undergoing laparoscopic hysteropexy was also encouraging; all subjects were free of symptomatic prolapse at 12 months. A prospective cohort study by Price et al. (2010) of 51 women undergoing laparoscopic hysteropexy with anterior and posterior arms reported one failure at 10-week follow-up. Pan et al. (2016) in a retrospective cohort study reported outcomes at a mean follow-up of 33 months ($n = 65$ hysteropexy and $n = 34$ hysterectomy). No mesh erosions were noted in either group. Success was higher in the hysterectomy group, although it did not reach statistical significance (88% vs. 72%, $P = 0.07$). Subjective satisfaction rate was higher in the hysterectomy with sacrocolpopexy (92% vs. 100%, $P < 0.001$). Ten women required retreatment with either pessary ($n = 9$) or reoperation ($n = 1$) in the hysteropexy groups compared with no retreatment in the hysterectomy groups (Pan et al., 2016).

Robotic-assisted laparoscopic sacrohysteropexy allows three-dimensional (3D) viewing, suturing, and dissection capacity; has increased maneuvering capability; and is minimally invasive (Tola et al., 2015). It provides good hemostasis, shorter hospitalization times, less morbidity and postoperative pain, but it is an expensive method (Geller et al., 2008). Seror et al. (2012) reported that better long-term results could be achieved with improved suturing and dissection. The long-term effects of robotic-assisted laparoscopic sacrohysteropexy have been found to be comparable with abdominal operations. Robotic-assisted laparoscopic sacrohysteropexy has been described in a study by Mourik et al. (2012). In this cohort that included 50 women and a follow-up to 29 months, women undergoing robotic-assisted laparoscopic sacrohysteropexy had significant improvement in QoL. Subjective cure rates were 95% (Mourik et al., 2012). In a small retrospective cohort of 15 women undergoing robotic-assisted laparoscopic sacrocolpopexy, Lee et al. (2013) noted an objective success of 93% (14/15) and subjective success of 80% (12/15). The mean age of women was 51.8 years (28–64 years). No intraoperative complications were noted. The mean operating time was 159.4 minutes (130–201 minutes), and mean estimated blood loss was 35 mL (0–100 mL). The mean length of stay was 1.6 days (1–4 days), and mean length of follow-up was 10.8 months. Uterine prolapse improved in all 15 patients (Lee et al., 2013). In a prospective series Grimminck et al. reported that 81% (30/37) showed no recurrence of uterine prolapse at a follow-up of 5 years. In this same series they reported the overall success rate of POP was 89.2% (Grimminck et al., 2016).

Pregnancy data after uterine-sparing POP are limited. Women who have prolapse surgery should be counseled that the effects of pregnancy on uterine sparing procedures are not clear. Twenty-four (9.4%) of 257 women who underwent POP surgery became pregnant, of these, 6 had cesarean births, and 10 had vaginal births, 8 of which resulted in abortions (Maher et al., 2010). **There**

are not enough data to make a standard recommendation regarding the type of hysteropexy in women who desire future pregnancy, and there is not a recommended mode of delivery (Ridgeway, 2015).

Posterior Compartment Repair

Symptoms attributable to posterior compartment prolapse can be divided conceptually as herniation symptoms, defecatory dysfunction, and sexual dysfunction (Cundiff and Fenner, 2004). Herniation symptoms include vaginal bulging or even bleeding of the epithelium from excoriation. Symptoms of defecatory dysfunction include stool trapping requiring vaginal splinting or manual digitation, defecatory urgency, and constipation. Defecatory dysfunction does not include fecal incontinence. Some authors point out that it is important to differentiate among the causes of defecatory dysfunction as those attributable to outlet obstruction (specifically when caused by defects in the support of the posterior compartment, perineum and rectum, as well as anismus) and those attributable to motility disorders (Cundiff and Fenner, 2004). Outlet obstruction attributable to pelvic floor defects may be alleviated with surgical restoration of anatomy. However, motility disorders, which usually involve impaired transit of stool through the rectum and anus, are treated with dietary modifications and medication. Anismus, defined as the failure of the puborectalis to relax during defecation, often responds to biofeedback and pelvic floor physical therapy. In combined disorders, it is recommended that nonsurgical treatment for anismus or slow-transit constipation (most common disorder of motility) be treated before embarking on surgical intervention.

Sexual dysfunction, if present, is thought to be secondary to dyspareunia, although decreased desire and anorgasmia may also be contributing factors (Handa et al., 2004). Several authors have sought to identify patient factors that would predict who may benefit most from rectocele repair (Murthy et al., 1996; Watson et al., 1996). These include sensation of vaginal mass or bulge, need for digitalization (splinting) to complete rectal evacuation, non-emptying or partial emptying on defecography, and presence of a large rectocele. Sensation of incomplete emptying and constipation are not specific to rectoceles and may be associated with other disorders, including irritable rectum and slow transit constipation. **Patients should be counseled that surgical repair of the posterior compartment may likely reduce vaginal protrusion symptoms and decrease or eliminate the need for vaginal splinting. However, some patients**

may have persistence of constipation, because motility disorders and anismus can independently coexist with prolapse and persist after a seemingly successful repair.

Rectoceles can be approached transanally or transvaginally. Nieminen et al. (2004) randomized 30 patients to rectovaginal fascia plication or transanal repair. Both approaches resulted in a high rate of symptom resolution (93% for the vaginal approach vs. 73% for the transanal approach). However, the vaginal approach had better objective findings and a lower rate of prolapse recurrence (7% vs. 66%). The traditional posterior colporrhaphy was devised in the 19th century to treat perineal tears, which occurred during vaginal delivery. The original description involved plicating the pubococcygeus muscles and the posterior vaginal wall with reconstruction of the perineal body, which was termed posterior colpoperineorrhaphy (Cundiff and Fenner, 2004). This resulted in a rigid inferior shelf, reduced the herniation of the posterior wall, and aided in preventing descensus of the vaginal vault or uterus. In 1961 Francis and Jeffcoate reported a high incidence of dyspareunia after colporrhaphy with levator plication. In their series of 243 women, 50% developed postoperative dyspareunia. In addition, there is evidence to suggest that traditional posterior colporrhaphy with levator plication may worsen defecatory symptoms. Kahn and Stanton (1997) reported increased symptoms of fecal incontinence, constipation, incomplete evacuation, and dyspareunia postoperatively. **Because of the increase in dyspareunia postoperatively, plication of the levator ani muscles has largely been abandoned. Site-specific repairs and midline fascial plication without levator ani plication have emerged as the predominant surgical treatments of a rectocele.** Level 1 and Level 2 evidence support the superior objective outcomes of midline posterior plication without levatorplasty compared with site-specific repairs.

Posterior Colporrhaphy Technique

For the posterior colporrhaphy technique (Fig. 124.35), the patient is placed into dorsal lithotomy position. However, if a patient requires an anterior or middle compartment repair, it should be performed first (Rovner and Ginsberg, 2001). The anterior wall can be retracted with a Heaney or Lone Star retractor with hooks to improve visualization. Hydrodissection may be accomplished by injecting saline or a local anesthetic with or without epinephrine. A midline incision is made through the posterior vaginal epithelium. For a high rectocele the incision may be as high as the vaginal apex (cuff); for smaller rectoceles the incision is started at the most caudal position. The rectovaginal fascia (muscularis) is separated from the vaginal epithelium with Metzenbaum scissors. The tips of the scissors should be pointed toward the vaginal epithelium to avoid rectal injury. The dissection proceeds laterally until the pararectal attachments to the pelvic sidewall are visualized. In cases of large posterior defects, a purse-string suture of 2-0 or 3-0 absorbable suture may be placed at the base of the rectal herniation to reduce it; however, care should be taken to avoid foreshortening the posterior wall cephalad to caudad. In addition, this acts to bring the attenuated rectovaginal fascia together to aid in its re-approximation. The rectovaginal fascia is then plicated in the midline with either interrupted or continuous 2-0 absorbable sutures. Care should be taken to avoid excessive lateral placement or wide spacing of these sutures; this may result in overtightening or painful ridges along the posterior vaginal wall. Suture placement is continued distally and incorporated into the perineal body re-approximation. The excess vaginal epithelium is judiciously trimmed and closed with a running absorbable 2-0 suture. A perineorrhaphy may also be performed before the vaginal epithelium is closed if the introital laxity dictates and care is taken to avoid overtightening.

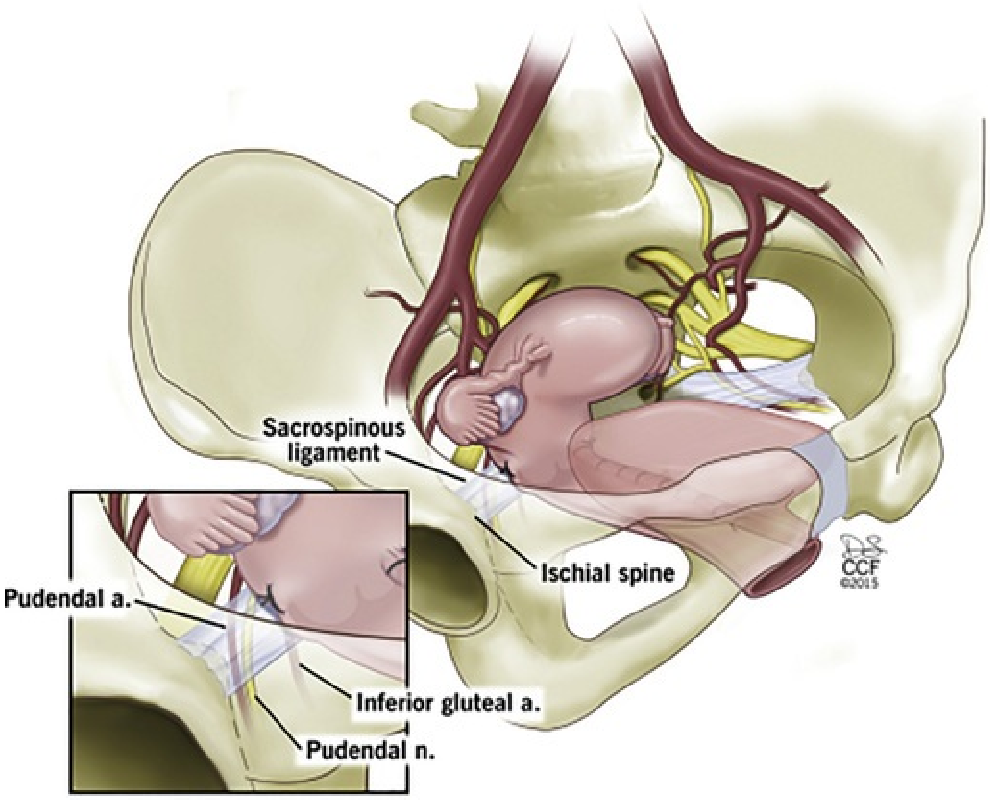

FIG. 124.35 Native tissue sacrospinous hysteropexy with the posterior cervix attached to the right sacrospinous ligament and anterior colporrhaphy. (From Ridgeway, BM: Does prolapse equal hysterectomy? The role of uterine conservation in women with uterovaginal prolapse. *Am J Obstetr Gynecol* 213[6]:802–809, 2015.)

Site Specific Repair: Technique.

To minimize complications associated with posterior colporrhaphy, a site-specific defect repair was described. Richardson (1993) described discrete defects in the rectovaginal fascia found in patients undergoing posterior colporrhaphy and cadaveric dissections. He found that the most common defect was the transverse configuration, separating the vaginal septum from the perineal body (Figs. 124.36 through 124.38). This essentially results in a separation of the rectovaginal fascia from the perineal body. The goal of the site-specific repair is to restore the anatomy by closing these discrete defects.

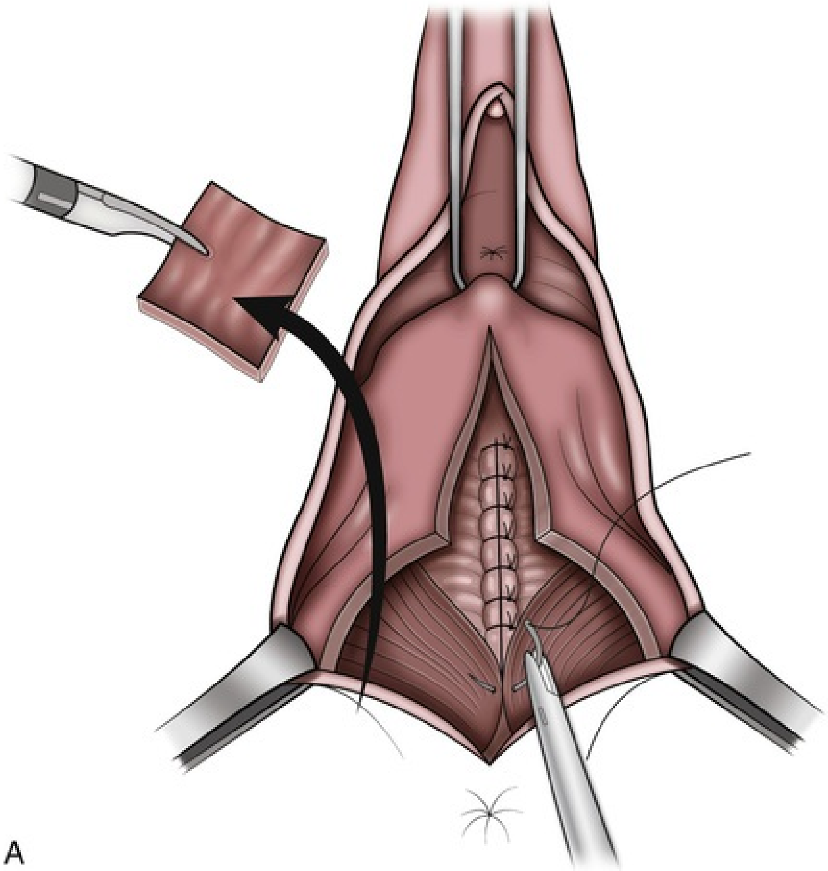
FIG. 124.36 Sacrohysteropexy using anterior and posterior mesh. The two arms of the anterior mesh exit the broad ligament. They are secured with the posterior mesh to the anterior longitudinal ligament of the sacrum. (From Ridgeway BM: Does prolapse equal hysterectomy? The role of uterine conservation in women with uterovaginal prolapse*. Am J Obstetr Gynecol* 213[6]:802–809, 2015.)



A

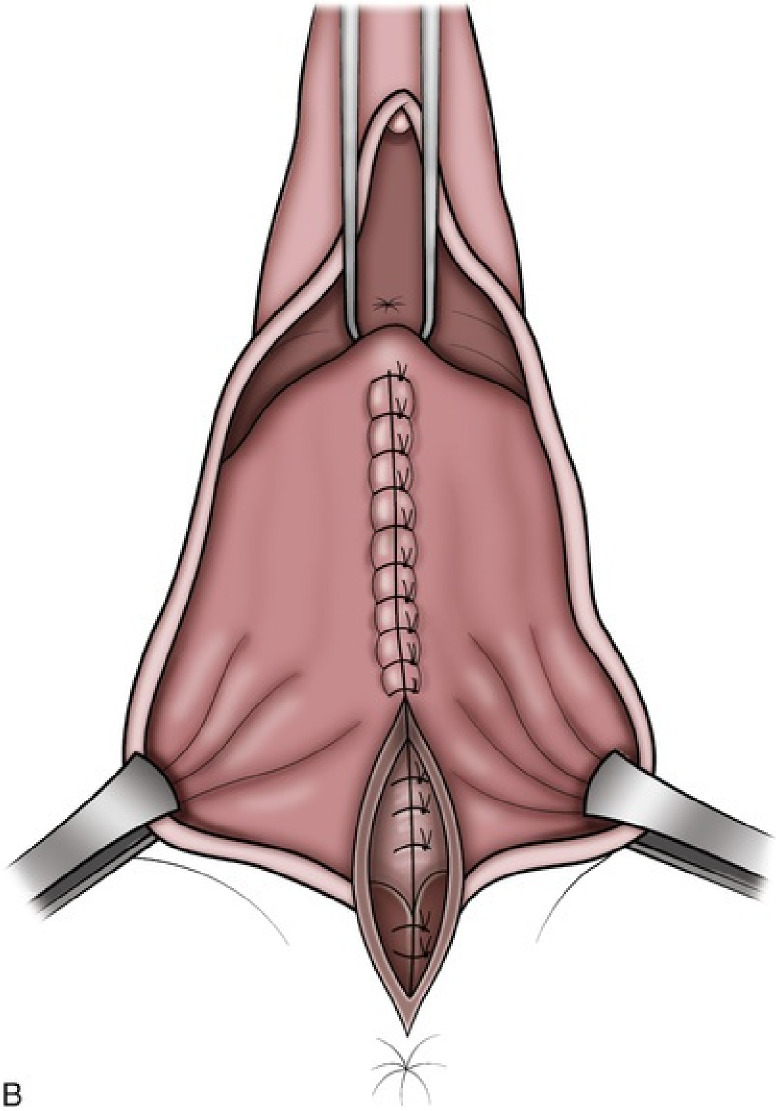


FIG. 124.37 (A and B) Technique of posterior colporrhaphy with rectovaginal tissue plication. (From Ginsberg D: Treatment of vaginal wall prolapse. In Goldman H, Vasabada S, editors: *Female urology: a practical clinical guide*, Totowa, NJ, 2007, Humana Press, pp 281–296.)

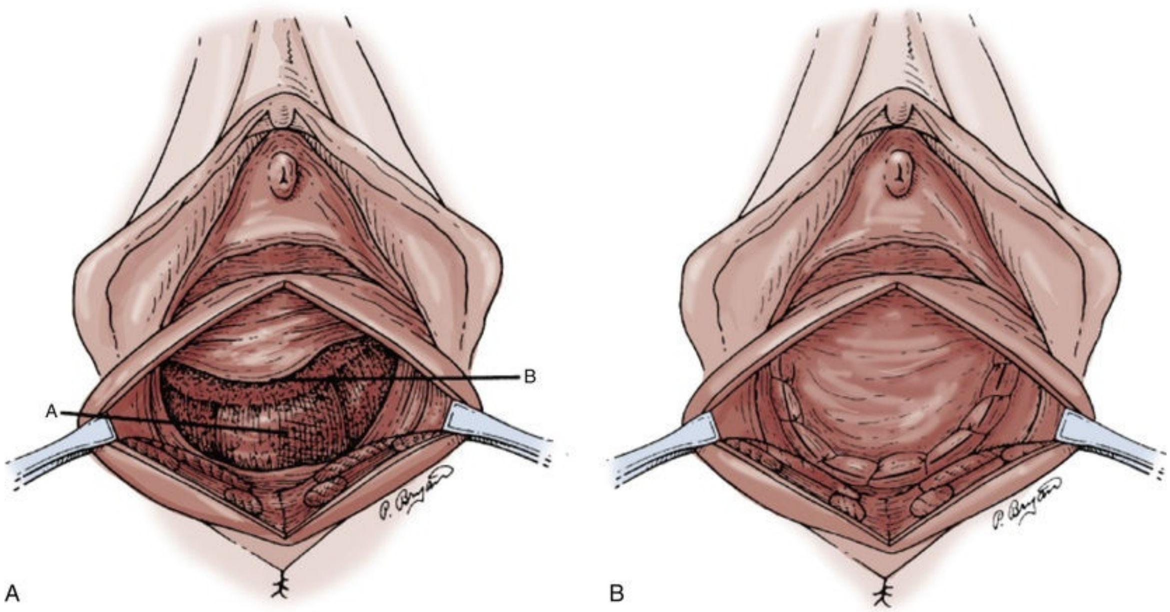

FIG. 124.38 Site-specific rectocele repair. A low transverse defect is identified and repaired primarily. (From Richardson AC: The rectovaginal septum revisited: its relationship to rectocele and its importance in rectocele repair. *Clin Obstet Gynecol* 36:976–983, 1993.)

A midline incision is made on the posterior vaginal epithelium. For a high rectocele the incision may be as high as the vaginal apex; for smaller rectoceles the incision is started at the most caudal position. The rectovaginal fascia (muscularis) is separated through a virtually bloodless plane from the vaginal epithelium. The index finger of the nondominant hand is then inserted into the rectum to facilitate identification of the fascial defect. The defect is closed with absorbable interrupted sutures. The excess vaginal epithelium is judicially trimmed, and the vaginal epithelium is closed with a running absorbable suture.

Perineorrhaphy: Technique.

A triangular incision at the mucocutaneous junction is removed (Rovner and Ginsberg, 2001). The triangular island of posterior vaginal wall is sharply removed from the pre-rectal levator fascia. Horizontal mattress sutures are used to approximate the attenuated perineal body fibromuscular tissue. Once these are brought together, the muscles of the urogenital diaphragm are reconstituted, and support is restored to the central tendon. It is important that a smooth contour be created along the suture line, because ridges may cause dyspareunia. A vaginal packing moistened with saline, antibiotic solution, cream, or gel may then then placed if warranted.

Posterior Colporrhaphy Results (Table 124.18).

Kahn and Stanton (1997) reported on the anatomic and functional results of posterior repair using levator plication. Both reported anatomic success; however, many patients complained of bowel symptoms and dyspareunia postoperatively (Kahn and Stanton, 1997). Because of the adverse events associated with levator plication, the technique has been abandoned by many surgeons.

Paraiso et al. (2006) randomized patients prospectively to posterior colporrhaphy (rectovaginal fascial plication), site-specific repair, or site-specific repair with porcine SIS graft. They found that posterior colporrhaphy and site-specific rectocele repair had similar functional and anatomic outcomes. The addition of the porcine-derived graft did not improve anatomic outcomes. Rates of dyspareunia did not differ when comparing all three groups. In a follow-up study of these same patients specifically looking at bowel symptoms, Gustilo-Ashby et al. (2007) found that anatomic cure was associated with a reduced risk of postoperative straining and sensation of incomplete bowel evacuation, but not with other bowel symptoms. They found that bowel symptoms, including feeling of incomplete emptying, straining to defecate, splinting to defecate, and fecal incontinence improved significantly after rectocele repair. Abramov et al. (2005) retrospectively studied patients with advanced posterior vaginal prolapse and compared patients who underwent traditional posterior colporrhaphy with those who underwent site-specific repair. They found that the recurrence of posterior defects was higher in the site-specific group compared with the midline plication of the rectovaginal fascia: 33% versus 14% for second degree and 11% versus 4% for third degree. In addition, recurrence of symptomatic rectocele was greater in the site-specific group (11% vs. 4%). Rates of de novo dyspareunia and postoperative bowel symptoms were the same in both groups. Maher et al. (2004b) prospectively studied the efficacy of posterior repair with plication of the rectovaginal fascia. They found that improved anatomic outcome correlated with improved functional outcomes. Eighty-seven percent no longer experienced obstructive defecation postoperatively. Significant improvements were seen in awareness of prolapse, obstructive defecation, straining to defecate, hard stools, dyspareunia, and digitations. Dyspareunia decreased from 37% to 5%. Singh et al. (2003) reported on a prospective study of 42 women evaluated for bowel, sexual, urinary, and prolapse symptoms as well as anatomic outcomes after fascial plication technique. At 6-week follow-up, 87% noted an improvement of bowel symptoms. At 18 months, they estimated the relief of vaginal symptoms to be between 73% and 92%. Sixty-five percent had improvement of the defecatory symptoms, and 38% had improvement of sexual discomfort. None of the patients reported de novo dyspareunia or bowel symptoms.

In contrast to the generalized repair of midline plication of the rectovaginal fascia, several authors have reported their experience with site-specific repair. Glavind and Madsen (2000) prospectively studied 67 patients who underwent a discrete repair. Of the 67 patients 64 were found to have a discrete defect, which was repaired, and in 3 there was an attenuation of the tissue. At 3-month follow-up, 85% of those who reported bowel symptoms preoperatively reported resolution of symptoms. Two patients (3%) had de novo dyspareunia. Porter et al. (1999) examined anatomic, functional, and QoL aspects of posterior colporrhaphy in a retrospective study. Improvement or cure was noted for pain or pressure, vaginal mass, splinting, and difficulty with defecation. Constipation did not significantly change. Preoperative dyspareunia improved in 73% of patients, worsened in 19%, and occurred de novo in 3 patients. Emotional health also improved, specifically thoughts of embarrassment and frustration. Kenton et al. (2007) reported on 66 patients who underwent site-specific repair; all patients had reattachment of the rectovaginal septum to the perineal body. Statistically significant symptom relief was noted in the realms of protrusion, manual evacuation, difficult defecation, and dyspareunia. Constipation was unchanged. Three patients developed de novo dyspareunia and 1 had de novo constipation. At 1 year, 7 of 11 patients who used manual evacuation preoperatively returned to doing so. The authors commented that this may be due to a functional decompensation of the rectum, which is not corrected surgically. Finally, Cundiff et al. (1998) reported on the anatomic and functional aspects of discrete fascial defect repair of the posterior compartment. At 12-month follow-up, 86% were noted to have a stage 1 or less prolapse. Splinting was eliminated in 63% of patients who reported this symptom preoperatively. The mean satisfaction score was 8.6 (10 highest). **The mean improvement did not correlate to the anatomic correction but did correlate with alleviation of defecatory symptoms, stressing the importance of symptom relief being of priority to the patient over anatomic correction.** The Fifth International Collaboration on Incontinence offered a grade B recommendation that Level 1 and 2 evidence suggest that midline plication posterior repair without levatorplasty may have superior objective outcomes compared with site-specific posterior repair, concluding that midline fascial plication without levatorplasty is the procedure of choice for posterior compartment prolapse (Karram and Maher, 2013). However, a 2018 Cochrane review concluded that because of the paucity of data and lack of good trials, the evidence was insufficient to draw conclusions about the relative effectiveness of these two procedures for posterior compartment prolapse (Mowat et al., 2018).

Interposition Graft Repairs of the Posterior Compartment

Synthetic mesh and biologic grafts have been used in posterior repairs, although data are lacking regarding routine use. Also, several authors caution against the use of synthetic materials in the posterior compartment because of the potential for dyspareunia and visceral erosion, favoring the use of biologic grafts (Chen et al., 2007). Kohli and Miklos (2003) reported anatomic outcomes on 43 patients who underwent a site-specific repair with cadaveric dermis; 30 were available for evaluation at an average of 12.9 months. The graft was fixed proximally to the vaginal apex, laterally to the levator ani muscles and distally to the perineal body. They reported a 93% success rate using the POP-Q grading system. Kobashi et al. (2005) reported using cadaveric fascia lata in 73 patients. With a mean follow-up of 13.7 months, there was an 83% to 89% improvement in symptoms. Ninety percent of those examined had a grade 0 rectocele by the Baden-Walker classification. Dell and O'Kelley (2005) used Pelvisoft, a fenestrated, porcine dermal acellular matrix, and reported no wound complications. Despite these encouraging results, Altman et al. (2005) reported on 29 patients using collagen mesh for symptomatic rectoceles. Twenty-three were available at 3-year follow-up; 41% had recurrence of stage 2 or greater, and 12 of 23 patients reported incomplete rectal evacuation. They advocated further study before recommending the routine use of graft augmented tissue repair. A 2018 Cochrane review found that between traditional repair and biologic graft groups the evidence is insufficient to show whether there were any differences in rates of awareness of prolapse (RR 1.09, 95% CI 0.45–2.62) or repeat surgery for any prolapse (RR 0.60, 95% CI 0.18–1.97). In addition, they point out that the existing trials demonstrate no conclusive evidence of a difference in rates of recurrent posterior vaginal wall prolapse between groups (RR 0.55, 95% CI 0.30–1.01). Postoperative complications were more common with biologic repair (RR 1.82, 95% CI 1.22–2.72 (Mowat et al., 2018).

A number of authors have used permanent mesh materials via a posterior approach. Although not advocated by the authors of this chapter, we will review some of the salient, albeit limited, results. The use of mesh in the posterior compartment was reviewed by the Fifth International Collaboration on Incontinence after a thorough literature search of all English-language literature through January 2012. Their conclusion with a grade B recommendation (mostly level 2 and 3 evidence) was that **no studies have shown any benefit of mesh overlay or augmentation over a suture repair for posterior vaginal wall prolapse** (Karram and Maher, 2013). Using permanent materials, multi-compartmental repairs are more commonly performed, extending from the sacrospinous ligament to the perineal body. de Tayrac et al. (2006) reported on 26 patients with a 2-year follow-up. Objective and subjective cure rates of 92.3% and 88%, respectively, were observed. Dwyer used a technique in which atrium mesh was attached to the sacrospinous ligament bilaterally and to the perineal body (Dwyer and O'Reilly, 2004). Fifty patients underwent posterior repair, 17 of which had anterior and posterior repair. No rectocele recurrence was seen at 13 months. Lim et al. (2005) reported using a composite Vicryl-Prolene mesh

(Vypro II, Ethicon) for correction of isolated rectoceles. In this descriptive study, 90 patients underwent loose placement of an interposition graft in the posterior compartment with no primary repair. Success was noted in 27 of 31 patients (87%) at minimum 6-month follow-up. Five patients with recurrence of the rectocele did not have prolapse in other compartments (Lim et al., 2005). Mercer-Jones et al. (2004) reported on 22 patients who underwent transperineal placement of either Vypro II or Prolene mesh; 77% reported moderate, good, or excellent results after mesh repair.

When deciding on treatment options for the posterior compartment, the surgeon and the patient should be aware that graft extrusion rates of 1.3% to 12% have been reported (de Tayrac et al. 2006, 2007; Kobashi et al., 2005; Lim et al., 2005), as well as dyspareunia rates as high as 60% (Milani et al., 2005).

Key Points: Posterior Compartment Repair

- Because motility disorders often coexist with posterior compartment prolapse, patients should be counseled that constipation may persist despite successful anatomic correction.
- Levator ani muscle plication should not be performed during rectocele repair because of the high risk of dyspareunia postoperatively.
- Despite the high cure rates seen with the use of mesh in the posterior compartment, dyspareunia and vaginal extrusion may be significant.
- Repair of the perineal body is often performed at the time of rectocele repair to recreate approximation of the rectovaginal connective tissues to the central tendon of the perineum.

Slings

Autologous, Biologic, Synthetic, and Mid-urethral

Alex Gomelsky MD, Roger R. Dmochowski MD, MMHC, FACS

The Evolution of Slings

Suburethral slings are currently considered the procedure of choice for the surgical correction of female stress urinary incontinence (SUI). Over the past century, a variety of autologous, allograft, xenograft, and synthetic materials and techniques have been employed for sling construction. The concept of slings for urethral support was first cited in 1907 by Von Giordano (1907) as a transplanted gracilis muscle graft wrapped around the urethra. Soon thereafter, additional sling procedures performed via the abdominal approach were described. Goebel (1910) tunneled pyramidalis muscle flaps through the retropubic space and sutured them together as a bolster under the bladder neck. Squier (1911) interposed the levator ani muscle between the urethra and the vagina, and Frangenheim (1914) incorporated the overlying rectus fascia in the pyramidalis muscle flap. Stoeckel (1917) further modified the above technique by adding plication of the bladder neck to the procedure. What was later called the Goebell-Frangenheim-Stoeckel technique was the first procedure to use a combined abdominovaginal approach. While additional modifications of autologous slings soon followed (Deming, 1926; Martius, 1929; Miller, 1932; Thompson, 1923), significant complications led to tepid enthusiasm for this surgical procedure. At the time, it was theorized that the transplanted muscle would retain its contractility and, in effect, act as a neo-sphincter to prevent SUI. Unfortunately, these procedures compressed the urethra and created a partial obstruction, commonly resulting in complications such as recurrent cystitis, urethral sloughing, fistula formation, and outlet obstruction.

A seminal modification of the autologous sling was published by Aldridge (1942), who first theorized that the abdominal muscles’ response to increased intra-abdominal pressure could be used anatomically to compress the urethra. Via an abdominovaginal approach, Aldridge detached strips of rectus fascia and external oblique aponeurosis laterally while leaving them attached medially. The 1.5-cm × 6-cm fascial strips were then tunneled through retropubic space and transferred into the vaginal incision. Ultimately, the strips of fascia were sutured together under the urethra after a bladder neck plication. Aldridge's “fundamental principle” was the decision to leave the sling attached to the rectus fascia in the midline, and was inspired by Price (1933), who used a fascia lata sling passed around the urethra and attached to the rectus muscle to cure incontinence in a woman with congenital absence of the sacrum and coccyx. In this article, Price stated that by attaching the sling to the rectus muscle, he was able to take full advantage of changes in the woman's posture and position to tighten or relax the sling at times when incontinence is most likely to occur. Although the technique for dynamic compression described by Price was very similar to the modern autologous pubovaginal sling (PVS), we now know that, with time and expected incorporation into the body, the sling becomes fixed and immobile in the retropubic space. Hence, eventual continence is no longer related to the sling's attachment over the rectus abdominis fascia. This is anecdotally supported by the fact that cutting these securing sutures in a woman with an obstructive sling months after surgery will have no impact on the sling's tension.

Aldridge's operation was notable for several advancements. First, he theorized that mobilization of any of the previously used muscles inevitably left the muscles denervated and devascularized. Thus, if the woman was continent, it was caused by obstruction from a urethral stricture. Second, he identified an “almost bloodless plane” on either side of the urethra, permitting atraumatic entry into the space of Retzius. Finally, he cautioned surgeons who were inexperienced in the anatomy of the anterior vaginal wall and bladder wall to avoid undertaking the procedure. Despite his warnings, the simplicity of the Aldridge sling led it to become a popular technique for many years, with reported short-term cure rates ranging from 78% to 93% (Jeffcoate, 1956; McIndoe et al., 1987; McLaren, 1957). McLaren (1968) reported an initial cure rate of 87% in 48 women and a 71% long-term cure rate in women followed up to 16 years.

Conversely, Aldridge's operation was associated with several drawbacks. Mobility of the fascial strips was frequently limited by their medial attachments, and no technique existed to prevent excessive tension under the bladder neck and proximal urethra. Also, it was not always possible to achieve sufficient length to pass the sling under the urethra. To address this deficiency, Studdiford (1944) bridged the gap left by the shortened fascia by attaching sutures to each strip of fascia and tying the sutures together under the bladder neck. Variations on the Aldridge sling over the next few decades involved attempts to minimize morbidity and obtain suitable sling material from women with multiple previous abdominal procedures. In the 1950s, Barnes (1950) and Hodgkinson and Kelly (1957) used round ligament, and Kasdon (1951) used uterine ligament. Narik and Palmrich (1962) described a variation on the Aldridge technique in which strips of external oblique aponeurosis were left attached to the pubic tubercle and tied together under the bladder neck. Of 51 women, 90% were cured of SUI in follow-up periods ranging from 6 to 24 months. Despite the improved length and support capabilities of the autologous sling modifications, complications were common, and overall interest in slings waned during the next 15 years. The interest in less-invasive bladder neck suspensions peaked during this period.

A renewed interest in slings emerged the late 1970s and early 1980s as long-term efficacy of the needle suspensions began to be questioned. Improving on Aldridge's technique, McGuire and Lytton (1978) left a strip of rectus fascia attached laterally on one side and tunneled the free end of the strip through the body of the rectus muscle to a suburethral location. The strip was then reattached to the other side of the rectus fascia. The authors reported an 80% to 95% overall success rate in patients with type III SUI (McGuire and Lytton, 1978; McGuire et al., 1987). McGuire et al. (1986) also first described using a 1-cm × 3-cm free rectus strip under the urethra in a series of female myelomeningocele patients. Blaivas and Olsson (1988) further modified McGuire's technique in their description of the modern bladder neck PVS in an effort to correct urethral hypermobility and modify the pressure transmission invoked by intra-abdominal pressure changes. The authors completely detached the rectus fascial strip at both ends and perforated the endopelvic fascia on either side of the urethra to gain access to the space of Retzius.

From 1991 to 1998, the PVS had surpassed needle suspensions and anterior urethropexies to become the predominant invasive surgical method for the treatment of SUI in the United States (Anger et al., 2009). Then in 1998, the U.S. Food and Drug Administration (FDA) approved the first mid-urethral sling (MUS) for use in women with SUI, and the rate of sling surgery increased by more than threefold (78.3 to 237.4 per 100,000 person-years) (Jonsson Funk et al., 2012). Likewise, in a 5% national random sample of Medicare claims from 2000 to 2011, there was a 29.7% increase in the number of sling procedures and a 59.5% decrease in bulking procedures (Chughtai et al., 2016). Unfortunately, as with most national databases, Medicare data are limited by the fact that the Common Procedural Terminology codes do not reveal the exact type of sling that is placed. However, many authors have inferred that the dramatic acceleration in sling surgeries is most likely a result of the increased popularity of the MUS (Oliphant et al., 2009; Wu et al., 2011).

Pathophysiology of Stress Urinary Incontinence and Sling Mechanism of Action

Several theories exist regarding the pathophysiology of SUI and the mechanism of action of sling procedures. A normal pelvic adaptation to an increase in intra-abdominal pressure involves a reflex contraction of the levator muscle and urogenital diaphragm, which elevates and compresses the proximal urethra by increasing the tension on the urethropelvic ligaments. Mid-urethral pressure and urethral closure pressure should rise concurrently with abdominal pressure, and, in the setting of intact urethral support, the increased intra-abdominal pressure is transmitted equally to the bladder and urethra. The net effect of these changes is increased outlet resistance during stress maneuvers resulting in continence. Conversely, when normal transmission of abdominal pressure to the urethra is lost, incontinence results.

Enhorning (1961) originally theorized that this pressure transmission occurs because the female urethra is intra-abdominal, much like in males where the proximal urethra lies cephalad to the urogenital diaphragm. In this model, women with poor anatomic support and urethral hypermobility develop SUI from proximal urethral descent during stress and less-efficient pressure transmission to the urethra. One problem with this theory was that the female urethra does not pass through a solid tissue layer, and only the proximal one-third of the female urethra is intra-abdominal, thus subject to transmitted pressure changes.

DeLancey (1994) published a revised model that made a significant contribution to the current understanding of the continence mechanism. **DeLancey's proposal was that healthy women have a “suburethral hammock” attached laterally that supports the urethra. However, in women with SUI, there is a deficiency of this supporting layer that is evidenced by hypermobility of the bladder neck and urethra.** It was theorized that descent of these structures inferiorly allowed for unequal pressure transmission and subsequent SUI. **Therefore a PVS placed at the bladder neck can eliminate SUI by providing a strong layer of tissue that provides dynamic compression of the urethra during times of increased intra-abdominal**

pressure. This and other similar theories emphasize that urethral support is derived from attachments to the arcus tendineus fasciae pelvis (ATFP) and levator ani muscles.

A second seminal theory focuses on the mid-urethra as the linchpin for continence. Placement of the MUS in this location is partially based on the theories initially put forth by Ingelman-Sundberg (1953), who noted that the pubococcygeus muscles insert at the level of the mid-urethra just outside the vaginal epithelial wall and play a vital role in the mid-urethral continence mechanism. It was further postulated that this anatomic finding is important when considering methods to correct SUI. Decades later, Westby et al. (1982) and Asmussen and Ulmsten (1983) demonstrated that **maximum urethral closure pressure (MUCP) occurs at the mid-urethra in continent women,** and this phenomenon is most likely caused by the combined contribution of anatomic structures in this location.

Based on the aforementioned theories and other published experiments, **Petros and Ulmsten** (1990) **proposed a unifying concept called the *integral theory,*** which posited that adequate function of the pubourethral ligaments, suburethral vaginal hammock, and pubococcygeus muscles was the most important factor for preservation of continence in women. They postulated that injury to any of these three components from surgery, parturition, aging, or hormonal deprivation could lead to impaired mid-urethral function and subsequent urinary incontinence. In one of the studies used as the basis for the integral theory, Ulmsten et al. (1987) performed a biopsy of the skin and round ligament of eight continent women and seven incontinent women. The researchers found that the tissues of incontinent women contained 40% less collagen and concluded that weakness of the connective tissue supporting the urethra secondary to the loss of collagen may contribute to incontinence.

The Age of the Mid-Urethral Sling

Ulmsten and Petros (1995) applied the integral theory to the development of the first retropubic synthetic MUS, which they termed an *intravaginal slingplasty.* In this initial report, 78% of 50 women undergoing a synthetic polymer sling achieved complete cure of SUI, and no complications were reported. **Ulmsten et al.** (1998) **changed the name of the procedure to the *tension-free vaginal tape* (TVT)** and reported this surgical technique's safety and efficacy prospectively. In this multicenter study, 91% of 131 women were cured of their incontinence, and two women developed transient urinary retention that resolved. One woman required “a small adjustment” of the MUS via a vaginal incision, and other complications included hematomas (2), mesh perforation of the bladder recognized at the time of surgery (1), and, although vaginal mesh exposure cannot be corroborated, one woman developed a wound infection requiring a minor surgical procedure and vaginal estrogen. It was this first multicenter MUS trial that was also among the first to report two of the unique and troublesome complications of MUS surgery: mesh perforation of the urinary tract and mesh exposure.

In an effort to minimize the potential for perforation of the urinary tract, bowel, or neurovascular structures, Delorme (2001) introduced the transobturator MUS approach. In his initial report, 97.5% of 40 women were cured of their incontinence, and only one woman experienced a complication. Initially, many proponents of the transobturator sling believed that there was no need to perform a cystoscopy after trocar passage; however, the American Urological Association (AUA) SUI guideline states that “intraoperative cystoscopy should be performed with mid-urethral slings or fascial pubovaginal slings to confirm the integrity of the lower urinary tract and the absence of a foreign body within the bladder or urethra” (Kobashi et al., 2017). Ten years after the introduction of the MUS, **Richter et al.** (2010) **published a study demonstrating that retropubic and transobturator MUS procedures were similarly efficacious and generally safe.** More recently, the AUA/SUFU Guideline made a Moderate Recommendation based on Grade A evidence that either the retropubic or transobturator MUS may be offered to index patients electing surgery for SUI (Kobashi et al., 2017).

The most recent step in the evolution of the sling came in 2006 when the FDA approved the first single-incision MUS (SIMS), a procedure that is performed completely through a vaginal approach without the need for skin entry (Abdel-Fattah et al., 2011). Although the risk for bladder or urethral perforation is low, intraoperative cystoscopy is still recommended to rule out injury. Since the last version of this chapter, significant outcome data have emerged for the SIMS leading to a Conditional Recommendation based on Grade B evidence in the AUA/SUFU guideline (Kobashi et al., 2017). While physicians may offer the SIMS to index patients undergoing MUS surgery, some of the data were deemed immature and inconsistent. This procedure will be presented later in this chapter.

Over the past decade, numerous studies have consistently demonstrated the efficacy and safety of various types of sling procedures for the treatment of female SUI. During the same time frame, several regulatory and professional organizations have raised concerns regarding synthetic mesh exposure and perforation complications unique to synthetic mesh materials, biologic grafts, and the specialized tools used in their placement (Novara et al., 2008). The FDA has responded by releasing two warnings in 2008 and 2011, and, although most of these concerns are related to graft materials used in transvaginal pelvic organ prolapse (POP) surgery, suburethral slings have been implicated by technical similarities. Ultimately, these concerns have led to the reclassification of transvaginal meshes used for POP repair as Class III devices requiring more extensive testing, regulatory oversight, and postmarket surveillance. This topic is of great importance to pelvic surgeons and their patients and will be discussed in further detail later in this chapter.

In the spirit of consistency, we will use the terminology developed by the International Urogynecological Association (IUGA) and the International Continence Society (ICS) for complications stemming from insertion of synthetic and biologic materials during female pelvic surgery (Haylen et al., 2011). According to this report, synthetic mesh is termed a *prosthesis*, and a biologic implant is termed a *graft*. Mesh located in the lower urinary tract is termed a *perforation*, and extrusion of mesh through the skin or vagina is termed *exposure*.

Key Points: Evolution of Slings

- Early theories regarding the cause of stress incontinence were focused on the unequal transmission of pressure to the bladder and urethra, urethral hypermobility, and the excessively inferior location of the urethra.

- Later theories emphasized the importance of the pubourethral ligaments, the suburethral vaginal hammock, and the pubococcygeus muscle as vital support structures for the proximal and mid-urethra.
- Based on these theories, pubovaginal slings are placed under mild tension at the bladder neck to reestablish the suburethral hammock, and mid-urethral slings are placed loosely at the mid-urethra to prevent movement of the posterior urethral wall.

Preoperative Assessment

The goal of a diagnostic evaluation in an incontinent woman is to characterize the type of incontinence, assess the contribution of comorbid medical conditions, elucidate the differential diagnoses, and discover prognostic information that will aid in the selection of treatment. The AUA guideline on the surgical treatment of female SUI stated that the following are the components of an initial evaluation of a woman with SUI who is desiring surgical intervention (Clinical Principle): focused history, including assessment of bother (e.g., via validated questionnaire), focused physical examination (including pelvic examination), objective demonstration of SUI with a comfortably full bladder (e.g., cough or Valsalva stress test), assessment of postvoid residual (PVR) urine volume (any method), and urinalysis (Kobashi et al., 2017). For completeness, it is important to mention that the European Association of Urology (EAU) guidelines on both assessment, nonsurgical treatment (Nambiar et al., 2018), and surgical treatment (Lucas et al., 2013) of urinary incontinence have also been published.

The evaluation of urinary incontinence begins with a thorough history focused on the onset, frequency, character, and severity of the incontinence, as well as other storage and voiding symptoms. Elucidating factors that worsen the woman's incontinence, such as sexual intercourse or exercise, is also important. **It is likewise critical to accurately assess the degree of a woman's baseline urinary urgency, as this specific symptom correlates with poorer outcomes after sling surgery** (Richter et al., 2008). The remainder of the history should focus on the evaluation of other factors that can impact bladder and urethral function, such as neurologic diseases, medications, prior surgeries, and pelvic radiation. Also, it is important to query the woman about problems related to fecal incontinence or defecation.

A focused neurourologic examination and pelvic examination should be performed on any woman with complaints of urinary incontinence. Uncovering physical findings of a neurologic or musculoskeletal disorder may aid in the treatment of a woman's incontinence symptoms. The pelvic examination may uncover correctable anatomic abnormalities that can contribute to incontinence, such as a vesicovaginal fistula and any abnormalities that are the result of urinary incontinence such as vaginal epithelial irritation. The examination should evaluate the following components, both at rest and with provocative maneuvers (i.e., Valsalva and coughing): vaginal anatomy, including the urethral meatus and vaginal support (i.e., POP); quality of vaginal tissues, including the presence of tissue atrophy and irritation; the degree of urethrovesical hypermobility; and any other associated findings, such as the presence of fistulae, foreign materials, or other anatomic abnormalities. During the examination, the patient should be asked to perform Valsalva maneuvers to reveal or emphasize POP, urethral hypermobility, and SUI. Although the usefulness of this test is controversial, a woman is considered to have urethral hypermobility if a Q-tip inserted into the urethra moves more than 30 degrees from baseline during abdominal straining (Bergman and Bhatia, 1987). Lastly, if a supine stress test with a full bladder does not demonstrate urinary incontinence, then a standing stress test should be performed.

Based on the AUA SUI guideline, **a urinalysis and measurement of PVR volume should be performed in all women, but more extensive imaging is not a part of the initial evaluation of a woman with a complaint of SUI.** It was the panel's expert opinion that physicians should perform additional evaluations in some women with abnormal findings in the history, physical examination, or urinalysis (Kobashi et al., 2017). These situations include: an inability to make a definitive diagnosis based on symptoms and initial evaluation; inability to objectively demonstrate SUI; known or suspected neurogenic lower urinary tract dysfunction (e.g., multiple sclerosis); abnormal urinalysis (e.g. unexplained hematuria or pyuria); urgency-predominant mixed urinary incontinence (MUI); elevated PVR per clinician judgement; high-grade POP (POP-Q stage ≥3) if SUI is not demonstrated by POP reduction; and evidence of significant voiding dysfunction. The panel concluded that additional evaluation may be performed in women with concomitant overactive bladder (OAB) symptoms, those with failure of previous anti-incontinence surgery, and those with previous surgery for POP.

Additional testing may include radiographic evaluation, cystoscopy, and urodynamic studies (UDS). Radiography of the upper urinary tract may be useful in women with concomitant hematuria or suspected neurogenic dysfunction. Likewise, magnetic resonance imaging (MRI) of the head, spine, and pelvis may be useful to detect spinal cord or brain lesions. The panel concluded that cystoscopy should not be performed in the evaluation of SUI unless there is a concern for urinary tract abnormalities, such as neoplasia or foreign body.

The necessity and benefit of preoperative urodynamic evaluation, including filling cystometrogram, measurement of leak point pressures, electromyography, and pressure-flow studies, is an area of controversy. The AUA SUI guideline panel concluded that **urodynamics may be omitted in the index patient when SUI is clearly demonstrated (Conditional Recommendation; Grade B level of evidence).** This statement is predominantly based on the findings of the ValUE trial that randomized women with SUI or stress-predominant MUI to urodynamics or clinical evaluation only before anti-incontinence surgery (Nager et al., 2012). In this multicenter, randomized, noninferiority trial of 630 women, the authors concluded that preoperative office evaluation alone was not inferior to evaluation with urodynamic testing for 1-year outcomes after SUI surgery in women with uncomplicated, demonstrable SUI. Other factors cited as evidence against routine UDS are the somewhat invasive nature of the studies and the considerable costs incurred. In a secondary analysis of the ValUE trial, Norton et al. (2016) found that the average cost of urodynamic evaluation per woman exceeded $300, which extrapolated to a US expenditure of $13 to $33 million annually.

On the other hand, proponents of preoperative urodynamics cite this evaluation as the only way of definitively diagnosing intrinsic sphincter deficiency (ISD) before surgery. While no study has found that urodynamic evaluation definitively predicts postoperative outcomes for uncomplicated SUI, at least two studies have suggested that women in the lower quartile of Valsalva leak point pressure (VLPP) or MUCP measurement have poorer outcomes after transobturator MUS (Nager et al., 2011; Schierlitz et al., 2012). Likewise, poor urethral function diagnosed on urodynamics predicted a twofold increase in surgical failure at 1 year after retropubic and transobturator MUS in the TOMUS (Trial of Mid-Urethral Slings) trial (Richter et al., 2010). Additionally, the study design of the ValUE trial has been called into question. As the study only sought to include women with uncomplicated SUI, the finding that 85% of the 4000 women screened were ineligible for study inclusion may indicate that the overwhelming majority of women do not have uncomplicated SUI. Furthermore, 97% of the treating physicians were fellowship-trained, indicating potentially less need for rigorous urodynamic testing.

It was the expert opinion of the panel that urodynamics may be performed in the nonindex patient, specifically those with: history of prior anti-incontinence or POP surgery; mismatch between subjective and objective measures; significant voiding dysfunction, urge-predominant MUI, urgency, urgency urinary incontinence (UUI), or OAB; elevated PVR; unconfirmed SUI; and neurogenic lower urinary tract dysfunction. It goes without saying that this step of the evaluation is dependent on the willingness of the patient to undergo the studies and the possibility that additional evaluation may alter or better define treatment options. In those women with significant POP, **urodynamic testing should be performed with and without POP reduction (e.g., with sponge stick or pessary).**

One of the goals of urodynamics is to evaluate urethral function. In women with SUI, low MUCP and abdominal leak point pressure (ALPP) are often used as indicators of urethral dysfunction. McGuire looked at the urodynamic properties of women in whom anti-incontinence surgeries had failed and determined that an **MUCP less than 20 cm H_2O was indicative of type III SUI (now known as ISD)** (McGuire, 1981). Several years later, Sand et al. (1987) performed urodynamic studies on 86 women undergoing modified Burch colposuspensions and determined that women with MUCP less than or equal to 20 cm H_2O had a significantly higher failure rate (54% vs. 18%) than women with MUCP greater than 20 cm H_2O. Other authors have also used an MUCP less than or equal to 20 cm H_2O to characterize a patient with severe urethral dysfunction (Clemons and La Sala, 2007; Fritel et al., 2008).

In addition to MUCP, **ALPP** can also give the clinician an objective measure of urethral dysfunction (McGuire et al., 1993). The authors performed urodynamic studies on 125 women with SUI and determined that an **ALPP less than 60 cm H_2O signified ISD, and an ALPP greater than 90 cm H_2O signified very little or no ISD. Since then, the definition of ISD has evolved from one based on strict urodynamic criteria to a clinical diagnosis. In understanding surgical treatment, it is essential to appreciate that all women with stress incontinence have some component of ISD.**

In addition to the outlet evaluation during urodynamic studies, **assessment of bladder pressure during filling and emptying yields valuable prognostic information about bladder function.** Most importantly, **the discovery of detrusor overactivity (DO) during bladder filling may have an impact on the decision to pursue a particular treatment option.** It has been theorized that both the stress leakage of urine into the proximal urethra (Kuru, 1965) and the traction on pelvic nerves that occurs when increased abdominal pressure is applied to weakened pelvic supportive tissue (Serels et al., 2000) can induce DO. Thus, there is the potential to improve the DO with anti-incontinence surgery in these women with “stress-induced DO.” However, there is the potential for existing DO and urinary urgency to worsen in women after otherwise uncomplicated anti-incontinence surgery. Thus, alternative or complementary treatment options should at the least be considered before proceeding with sling surgery in women with DO. A low cystometric bladder capacity and decreased compliance may also negatively affect the outcomes of sling surgery, and these factors should also be considered. Finally, as previously mentioned, the overall value of urodynamics in predicting outcomes after sling surgery is debatable (Nager et al., 2008, 2011).

Key Points: Preoperative Assessment

- At minimum, a woman being evaluated for urinary incontinence should undergo a focused history, physical examination, and objective confirmation of SUI. In addition, basic clinical tests such as urinalysis and PVR volume measurement should be performed.
- While cystoscopy should not be performed in women with uncomplicated SUI, this diagnostic modality and other radiographic imaging may be performed in those women with hematuria and when urinary tract abnormalities are suspected.
- Urodynamic studies may be omitted in women with uncomplicated SUI and stress-predominant MUI who desire surgical intervention. However, these studies may prove useful if the diagnosis of SUI is unclear or when there are concomitant complicating factors, such as significant urinary storage and voiding symptoms, history of prior lower urinary tract surgery, suspected neurogenic bladder dysfunction, or significant POP.
- Although slings are an effective treatment for both SUI and stress-predominant MUI, a thorough understanding and characterization of a woman's preoperative symptoms and bother will help guide counseling and treatment decisions.

Alternative Treatment Options

As urinary incontinence rarely impacts *quantity* of life, nonsurgical treatment options should be discussed with each woman. It was the expert opinion of the AUA SUI guideline panel that treatment options should be tailored to the individual patient, and patient bother should be taken into account in the decision for therapy (Kobashi et al., 2017). Initial nonsurgical (conservative) therapy includes patient education, behavioral and dietary modification, judicious fluid restriction, weight loss, and pelvic floor muscle training (PFMT) (Dallosso et al., 2003). There is significant evidence in the literature to support the efficacy of these treatment methods (Osborn et al., 2013). Subak et al. (2009) randomized 338 obese women to one of two different weight-loss programs, and, after 6 months, the two programs showed an average 8- and 1.6-kg weight loss with a corresponding significant 58% and 33% reduction in SUI (Subak et al., 2009). A recent review concluded that weight loss may have a salubrious impact on both SUI and OAB symptoms (Fuselier et al., 2018).

Kegel exercises and formal PFMT are other nonsurgical treatment options and are theorized to help with pelvic floor muscle strength and coordination. A Cochrane Database systematic review of 21 randomized and quasi-randomized trials of PFMT in women with SUI concluded that PFMT should be recommended to most women before surgical treatment (Dumoulin et al., 2015b). Compared with no treatment, women undergoing PFMT were more likely to experience cure of SUI (risk ratio [RR] 8.38; 95% confidence interval [CI] 3.68 to 19.07) and cure or improvement (RR 17.33; 95% CI 4.31 to 69.64). PFMT was also associated with cure of any type of incontinence (RR 5.5; 95% CI 2.87 to 10.52) or cure and improvement (RR 2.39; 95% CI 1.64–3.47). However, as with any exercise regimen, vigilance in continuing PFMT remains the key to its success. An expert-panel consensus of the State-of-the-Science Seminar on PFMT held before the 41st International Continence Society scientific meeting concluded that adherence to PFMT is central to short- and longer term symptom improvement (Dumoulin et al., 2015a). Additionally, pessaries and other vaginal and urethral devices have been shown to help with SUI in select individuals (Robert and Mainprize, 2002; Staskin et al., 1998).

The **submucosal injection of periurethral bulking agents** using a cystoscope is a minimally invasive treatment for SUI, albeit one with variable success rates and frequent need for retreatment. The discontinuation of bovine-derived cross-linked collagen in 2011 by its manufacturer has led to the increased use of several newer synthetic, permanent agents. However, a recent Cochrane systematic review concluded that there was limited evidence for the benefit of these agents (Kirchin et al., 2017). Nevertheless, because of the low risk for side effects, periurethral bulking remains a potential treatment option for many women who are not ready to undergo a more invasive surgical procedure.

Pubovaginal Sling (PVS)

As compared with a MUS, a PVS is placed at the bladder neck. It is a highly versatile surgical procedure for both uncomplicated and complicated SUI associated with a deficiency in a portion of the mid-urethral complex, urethral hypermobility, ISD, MUI, concomitant cystocele (Cross et al., 1997; Serels et al., 1999), urethral diverticula, and neurologic conditions (Austin et al., 2001). In women with neurogenic SUI, such as those with myelodysplasia, a PVS is effective for the SUI that may occur between clean intermittent catheterizations (CIC) once a thorough urodynamic evaluation has confirmed sufficient bladder capacity and compliance. A PVS may also aid in the reconstruction of the urethra after damage secondary to trauma, synthetic mesh (or graft) perforation, and iatrogenic hypospadias, or it can be used for interposition during urethral repairs of urethrovaginal fistulae or urethral diverticula (Blaivas and Heritz, 1996; Gormley et al., 1994; Leng and McGuire, 1998; McGuire and O'Connell, 1995). Likewise, a PVS is effective in treating recurrent SUI after failed retropubic suspensions or MUS placement (Beck et al., 1988; Petrou and Frank, 2001). Although many different sling materials and techniques have been described, the PVS using autologous fascia remains the gold standard for management of ALL forms of SUI.

Anatomy and Mechanics of a Pubovaginal Sling

Female SUI is caused by a combination of damage to the mid-urethral complex and ISD. Urethral hypermobility is a physical indication that the mid-urethral complex may not be functioning optimally. The female urethra is positioned under the pubic symphysis, and the pubourethral ligaments suspend the anterior urethral wall to the pubic arch. In cases of urethral hypermobility, Valsalva or other increases in intra-abdominal pressure cause the posterior wall of the urethra to slide away from the anterior urethral wall and, in turn, open the bladder neck and proximal urethra. Uneven pressure transmission combined with the opening of the bladder neck (funneling) cause a loss of urine with stress maneuvers. **ISD** arises from defects within the urethra proper, so that the urethral sphincter is unable to coapt and generate enough resting urethral closing pressure to maintain continence.

The female urethra is composed of four separate tissue layers that assist in keeping it closed. Compression from the middle muscular layer helps maintain the resting urethral closure mechanism, and the outer seromuscular layer augments this closing pressure. In normal circumstances, the resting urethral closing pressure of the internal sphincter exceeds the resting or Valsalva pressure exerted by the bladder. In addition, fast-twitch fibers of the external sphincter are responsible for a sudden voluntary contraction, and slow-twitch fibers provide continuous passive control by the involuntary guarding reflex during bladder filling. In addition to these structures, the integrity of the pelvic diaphragm is also dependent on the levator ani for continence control. Lastly, the urethropelvic ligament and pubocervical fascia provide support to the bladder neck and undersurface of the bladder, respectively, to prevent SUI (Vasavada and Rackley, 2009).

The PVS is positioned at the bladder neck to provide dynamic urethral compression without obstruction during times of increased intra-abdominal pressure. The ultimate goal is to provide adequate urethral coaptation and increase urethral responsiveness to abdominal pressure. This must be balanced against the risks for ischemia, retention, and erosion from unnecessary tension. **Blaivas and Olsson** (1988) **described the current version of the PVS and modified McGuire's technique by using a shorter free graft of rectus fascia whose tension could be adjusted.** It is the incorporation of the sling into the endopelvic fascia and subsequent fixation and fibrosis, rather than entry into the retropubic space, that prevents the sling from giving way after increases in intra-abdominal pressure. The approximately 2-cm width of the PVS ensures that there is sufficient support to provide the needed urethral compression and a cross-sectional area adequate to avoid the formation of a narrow constricting band.

Pubovaginal Sling Materials

Throughout the past century, multiple autologous, allograft, xenograft, and synthetic materials have been used for the construction of a PVS. The ideal material provides long-lasting suburethral support with minimal adverse effects. While an ideal implanted material should incorporate itself into the host with minimal tissue reaction, in reality, most materials promote organized fibrosis and reinforce the sphincteric mechanism through improved suburethral support. Theoretically, a greater degree of fibrosis leads to better clinical results (Bidmead and Cardozo, 2000; Woodruff et al., 2008); however, inflammatory infiltration can lead to rapid sling material degradation and possible tissue destruction with erosion (Bidmead and Cardozo, 2000). **Although the autologous sling is completely biocompatible and has rarely been associated with urethral perforation, biologic grafts and synthetic prosthetics had gained popularity because of decreased operative time, morbidity, pain, and length of hospital stay after surgery with these materials** (Niknejad et al., 2002).

Autologous Pubovaginal Slings

The most commonly used autologous materials are **rectus abdominis fascia** harvested from the abdominal wall and **fascia lata** harvested from the lateral thigh. Fitzgerald et al. (2000) reported that after sling placement, rectus fascial grafts undergo extensive remodeling and have abundant fibroblasts and connective tissue on biopsy specimens. Other authors have published similar findings. Woodruff et al. (2008) performed a histologic comparison of PVS materials (10 synthetic, 5 autologous, 5 allografts, and 4 xenografts) and noted that autologous materials were associated with the greatest degree of host fibroblast infiltration and neovascularization, but minimal inflammatory or foreign-body reaction. Analysis of explanted specimens up to 65 months after placement revealed that the autologous fascial grafts were consistently intact and displayed minimal gross degradation. **In addition to the inherent benefit of minimal inflammation, autologous tissue also carries a negligible risk for urethral erosion** (Webster and Gerridzen, 2003)**. Disadvantages of harvesting autologous fascia include an increase in operative time, hospital stay, postoperative pain, and harvest site complications**.

It is important to note that even if the rectus fascia harvest site is scarred and thickened from prior operations, the quality of rectus graft may not be ultimately compromised. Nevertheless, there are some instances, such as a prior ventral hernia repair, in which **fascia lata** is the preferred autologous material for PVS. This fascia is harvested from the thigh and has similar properties to rectus fascia (Beck et al., 1988; Latini et al., 2004). Like rectus fascia, fascia lata is completely biocompatible and is associated with minimal tissue reaction. Unlike rectus fascia, the **recovery time is reportedly less, and there is minimal risk for abdominal harvest site complications. However, harvesting fascia lata does require repositioning of the woman, additional operative time, and operating in an area unfamiliar to most pelvic surgeons** (Govier et al., 1997). Furthermore, thigh pain may be a short-term sequela. Wheatcroft et al. (1997)

reported that 67% of women had pain on walking for 1 week after fascia lata harvest, although Latini et al. (2004) reported that only 7% of women complained of pain at the incision site 1 week after harvest using a Crawford fascial stripper. Thigh muscle herniation has also been reported in the literature, but this appears to only occur when large strips of fascia are removed (Dubiel and Wigren, 1974; Wheatcroft et al., 1997). In these studies, the rate of thigh herniation was 51% (20 of 39) with a 10- to 20-cm fascial graft and 0% (0 of 24) with a 1.5-cm by 12- to 15-cm fascial graft.

Vaginal epithelium has also been used as an autologous source for sling construction. Raz et al. (1989) described use of in situ vaginal wall; however, this tissue may lack sufficient tensile strength, and there is a risk for epithelial inclusion cyst formation and vaginal shortening. Also, a lack of retropubic space dissection may mitigate the overall efficacy of this procedure (Appell, 2000; Ghoniem and Hassouna, 1998; Loughlin, 1998).

Pubovaginal Sling Allograft Materials

Cadaveric allografts used in many nonurologic surgical arenas (e.g., orthopedics, neurosurgery) were eventually adopted for SUI surgery. **Allograft slings are currently derived from either cadaveric fascia lata (CFL) or acellular human dermis.** After harvest, the allografts are processed by solvent dehydration or by lyophilization (freeze-drying) to remove genetic material and to prevent the transmission of infectious agents. Secondary sterilization may also be achieved by gamma radiation (Gomelsky et al., 2003). Unlike autologous materials, histologic analysis reveals that cadaveric dermis (CD) has minimal host fibroblast infiltration and neovascularity, particularly in the central aspects of the graft (Woodruff et al., 2008). In addition, gross examination may reveal disruption of the sling scaffold and significant graft thinning and degradation.

In general, **allografts are pliable, easy to use, and available in a variety of sizes. No specific allograft has been associated with a clinical advantage;** however, acellular dermis rehydrates in 0.9% saline more quickly than does cadaveric fascia lata (5 minutes vs. 15 to 30 minutes) (Gomelsky et al., 2003). In addition, biomechanical studies have shown that solvent-dehydrated cadaveric fascia lata and acellular dermis have a higher maximal load to failure than freeze-dried cadaveric fascia lata (Hinton et al., 1992; Lemer et al., 1999). More specifically, Lemer et al. (1999) theorized that ice crystal formation produced by tissue freezing disrupts the collagen matrices and causes decreased tissue integrity and durability.

Since allografts are harvested from cadavers, their use may be associated with a theoretical concern of transmitting illnesses such as the human immunodeficiency virus (HIV), hepatitis, and Creutzfeldt-Jakob disease (CJD). Since the onset of tissue screening in 1985, there has been one documented case of HIV transmission from a nonurologic tissue transplant. The estimated risk for acquiring tissue from a properly screened donor infected with HIV is 1 per 1,667,600 (Gallantine and Cespedes, 2002). A few cases of CJD have been reported after transplantation of cadaveric dura or corneas; however, skin obtained from animals infected with these prions has demonstrated no detectable infectious particles. Currently, the theoretical risk for developing CJD from a non-neural allograft is 1 in 3.5 million, and no cases of hepatitis or CJD have ever been attributed to the use of processed cadaveric fascia or dermis (Amundsen et al., 2000b; Gallantine and Cespedes, 2002). The theoretical risk for developing hepatitis from allograft material is unknown; however, two cases of hepatitis transmission have been reported in the musculoskeletal tissue transplantation literature, both occurring before the implementation of extensive donor screening for viruses and bacteria and the availability of serologic tests (Shutkin, 1954). Despite the low risk for disease transmission, human DNA has been detected in various allograft materials (Choe and Bell, 2001; Hathaway and Choe, 2002); however, the clinical significance of this finding is unknown.

Pubovaginal Sling Xenograft Materials

Xenograft use was common in the 1980s (Descurtins and Buchmann, 1982; Iosif, 1987) because of the materials’ immediate accessibility and minimal associated morbidity; however, xenografts for sling construction have met with decreasing popularity in recent years. Available xenografts are either **porcine (dermis, small intestinal submucosa (SIS), or bladder acellular matrix graft) or bovine (dermis or pericardium) in origin.** Modern processing techniques using diisocyanate to remove genetic material have made porcine grafts both safer and more pliable; however, in a rabbit model, there was significant loss of tensile strength after implantation (Dora et al., 2004). It is interesting to note that histopathologic analysis has shown porcine small intestinal submucosa (SIS) to contain growth factors that may reduce host-graft immunologic reaction and lessen tissue scarring (Wiedemann and Otto, 2004). Although most data support SIS as nonimmunogenic, animal studies by Thiel et al. (2005b) suggested that an intense inflammatory reaction occurs 30 to 90 days after subcutaneous implantation. In a report by Kalota (2004), 33% of 18 women experienced postoperative inflammation after an SIS PVS procedure. Konig et al. (2004) reported a single case of postoperative inflammation with abscess formation with SIS use, although Ho et al. (2004) reported a similar reaction in 6 of 10 women. In a series by John et al. (2008), all of the women had pain and erythema at the abdominal incision, and 2 developed abscesses. Of note, five of the six women with inflammatory responses were continent. Five women were treated conservatively, and one required abscess drainage. The exact cause of these complications is unknown but is likely related to a foreign-body reaction from the multilayered (8-ply) SIS material, a reactive manufacturing ingredient, or the tendency for suprapubic fat to produce an inflammatory reaction.

In 2001, Kubricht et al. (2001) showed that porcine SIS has less tensile strength than cadaveric fascia lata. Bovine pericardium has been available in a preparation cross-linked with glutaraldehyde or as a non–cross-linked acellular matrix (Gomelsky et al., 2003). Histopathologic comparison of sling materials by Woodruff et al. revealed porcine dermis to have no host fibroblast infiltration, no inflammatory reaction, and no foreign-body reaction (Woodruff et al., 2008). This study also showed that xenograft had the highest propensity to encapsulate, with the capsule around the porcine dermis isolating the graft from the periurethral tissue. The grafts were described as appearing similar to their original appearance at time of implantation.

Pubovaginal Sling Synthetic Prosthetic Materials

Kraats introduced the first synthetic sling (nylon) (Kraatz, 1953), and in the decades since, other synthetic materials have been used for sling construction. The advantages of synthetic material for PVS surgery are consistent quality, elimination of harvest site complications, decreased operative time, and an extensive supply of artificial graft material in multiple sizes and shapes. **Compared with biologic grafts, synthetic materials are more uniform, consistent, and durable. In addition, synthetic prosthetic materials are sterile, biocompatible, and noncarcinogenic** (Niknejad et al., 2002)**. On histopathologic comparison, synthetic materials demonstrate the least amount of degradation or disruption and the greatest amount of fibroblast and tissue ingrowth into the specimen** (Woodruff et al., 2008). Microscopically, synthetic materials are associated with a foreign-body reaction characterized by giant cells and occasional microcalcifications. This foreign-body reaction is not visible grossly, and no graft disruption or adverse effects to the host have occurred.

Artificial graft materials do have potential drawbacks, including graft infection, urinary tract perforation, and vaginal exposure. Along with patient characteristics, the chemical and physical properties of each artificial material determine how the sling will ultimately incorporate into the surrounding host tissue. The susceptibility to infection and poor integration in multifilament synthetic prostheses is proportional to the pore size of the materials (Amid, 1997; Niknejad et al., 2002). Tightly woven, microporous meshes typically admit small bacteria but exclude macrophages and polymorphonuclear leukocytes. Conversely, loosely woven, macroporous meshes allow tissue ingrowth and neovascularization without limiting cellular access. Tissue bonding to the mesh strengthens and supports the repair. Increased mesh stiffness or decreased pliability may also contribute to mesh exposure.

The classification by Amid (1997) used for synthetic materials in hernia surgery may be practically applied to urology as well (Table 125.1). The most frequently used materials are grouped into four types. Type I are totally macroporous prostheses containing pores greater than 75 µm, which is the pore size for admission of macrophages, fibroblasts, blood vessels, and collagen fibers (Bobyn et al., 1982; White, 1988; White et al., 1981). Type II materials are completely microporous prostheses commonly made from expanded polytetrafluoroethylene (ePTFE) and contain pores less than 10 µm in at least one dimension. Type III includes macroporous prostheses with multifilamentous or microporous components, and type IV includes biomaterials with submicronic pore size (Amid et al., 1992) (see Table 125.1). Amid (1997) proposed that the risk for infection and seroma formation was decreased by the use of type I mesh.

TABLE 125.1

Classification of Synthetic Materials

TYPE	DESCRIPTION	REPRESENTATIVE MATERIAL	BRANDS	NOTES
I	Pores >75 µm; macroporous	Polypropylene	Trelex Natural Mesh, Marlex, Prolene	Monofilament with open weave pattern
II	Pores <10 µm; microporous	ePTFE	Gore-Tex, Surgical Membrane,	Very flexible

			Dualmesh	
III	Macroporous with multifilamentous or microporous components	PTFE	Teflon	Multifilament
		PE	Mersilene (braided Dacron[a] mesh)	Multifilament fibers, very porous, becomes firmly embedded in native tissues
		PE impregnated with collagen matrix	ProteGen	Removed from market in 1999 secondary to high rate of vaginal exposure
		Braided polypropylene	Surgipro	
		Perforated ePTFE patch	Gore-Tex MycroMesh	
IV	Submicronic pore size	Silicone plus woven PE	Silastic[b]	Minimal tissue reaction, which facilitates removal or revision if necessary
		PE/Silastic laminated sheeting	Celgard[c]	

[a] Dacron is polyethylene terephthalate (polyester) and is manufactured by DuPont USA.

[b] Silastic is a silicone polymer manufactured by Dow Corning Corporation in Midland, MI.

[c] Celgard is manufactured by Celgard LLC in Charlotte, NC.

ePTFE, Expanded polytetrafluoroethylene; *PE,* polyethylene terephthalate; *PTFE,* polytetrafluoroethylene.

Modified from Amid PK. Classification of biomaterials and their related complications in abdominal wall hernia surgery. *Hernia* 1:15–21, 1997; Niknejad K, Plzak LS, Staskin DR, et al. Autologous and synthetic urethral slings for female incontinence. *Urol Clin North Am* 29:597–611, 2002.

The most commonly used synthetic material for all slings is polypropylene mesh (type I). It is composed of loosely woven strands of polypropylene and has a pore size greater than 80 µm, permitting passage of macrophages and excellent host tissue ingrowth (Kobashi et al., 2002). Because of the propensity of many synthetic materials to become exposed or to perforate during PVS placement at the bladder neck, their mention in this chapter is predominantly of historical value. At present, synthetic materials are employed for loose sling placement at the mid-urethra (Niknejad et al., 2002).

Key Points: Pubovaginal Sling Materials

- The ideal material for the construction of a PVS is sterile, biocompatible, noncarcinogenic, and consistent in quality.
- The implanted material should be incorporated into the host with minimal tissue reaction and provide long-lasting suburethral support with minimal complications.
- Autologous materials remain the gold standard for PVS and are associated with no tissue reaction and negligible chance of urethral perforation. Other biomaterials have been used in an attempt to shorten operative time, hospital stay, and postoperative recovery.
- Tissue-processing techniques for allografts vary and may disrupt the microstructure thereby affecting ultimate graft strength.
- Xenografts have less tensile strength than allografts in situ and have the highest propensity to encapsulate. Like allografts, processing of these materials may vary significantly.
- Synthetic materials, as a whole, are characterized by significant inflammatory and foreign-body reactions and are associated with higher rates of graft infection and perforation. These prostheses are suboptimal for placement at the bladder neck.

Pubovaginal Sling Operative Procedure

Counseling

The risks associated with surgery in general should be discussed during the informed consent process. If a synthetic prosthesis or xenograft is being used, surgeons should thoroughly counsel their patients about the permanent nature of these products and the unique and sometimes serious complications related to their use. In our opinion, this step is paramount because many patients and their families have increased awareness of the **potential dangers of synthetic mesh.** Women should also be counseled about the risk for **transient and permanent voiding dysfunction after surgery.** This should include a discussion of postoperative difficulty emptying the bladder and de novo urgency and frequency. Preoperative instruction in performing CIC in select patients may minimize the need for an indwelling urethral catheter postoperatively.

Anesthesia, Patient Positioning, and Preparation

PVS placement may be performed under spinal or general anesthesia, and is ultimately based on patient, surgeon, and anesthesia provider consensus. Sling surgery is classified as a clean-contaminated case. An AUA Best Practice Policy Statement recommends the preoperative administration of a single dose of a first- or second-generation cephalosporin or an aminoglycoside plus metronidazole or clindamycin (Wolf et al., 2008). While fluoroquinolones have been previously listed as alternative options for preoperative antibiotic prophylaxis, recent changes have emerged in product labeling. On July 26, 2016, the FDA revised the black box warning, the FDA's strongest warning, to address serious safety issues that may result from the use of fluoroquinolones. The FDA specified that fluoroquinolones have serious side effects that outweigh the benefits in the use of conditions, such as uncomplicated UTIs, in patients for which other treatment options may be effective. The FDA did not comment on the use of fluoroquinolone antibiotics before outpatient procedures or the routine use perioperatively; however, because of the side-effect warning, physicians should consider switching to a different antibiotic in surgery or before a procedure on case-by-case basis.

We routinely place bilateral lower extremity intermittent pneumatic compression (IPC) devices before administration of anesthesia. The AUA Best Practice Policy Statement for the Prevention of Deep Venous Thrombosis in Patients Undergoing Urologic Surgery states that, for incontinence surgery, the use of IPC devices, low-dose unfractionated heparin, or low-molecular-weight heparin should be based on individual patient and procedural risk factors (Forrest et al., 2009).

The patient is placed in the dorsal lithotomy position, and care is taken to minimize the potential for lower extremity neural injury. Although the overall incidence is low (1.8%), Bohrer et al. observed 14 peripheral nerve injuries in 11 patients, with lateral femoral cutaneous (5), femoral (5), common fibular (1), ilioinguinal/iliohypogastric (1), saphenous (1), and genitofemoral (1) nerves affected (Bohrer et al., 2009). Fortunately, complete resolution of neuropathic symptoms occurred in all but one woman at a median time to symptom resolution of 31.5 days (range, 1 day to 6 months). The abdomen (from the umbilicus down) and vagina are prepared and draped in sterile fashion. In the United States, povidone-iodine is the most commonly used antiseptic for vaginal preparation; however, in other countries this is may not be the case (American College of Obstetricians and Gynecologists [ACOG], 2013). In September 2013, ACOG released a committee opinion that chlorhexidine gluconate solutions containing 4% alcohol or less were both safe and effective for vaginal preparation (off-label use).

A weighted speculum is placed in the vagina, and an 18-Fr Foley catheter is inserted into the urethra. The patient should be placed in a moderate Trendelenburg position; for optimal visualization during vaginal dissection, the surgeon may benefit from a headlight. A vaginal ring retractor may be used to retract the labia majora and, later in the case, to retract the incision, further improving visualization and ease of dissection.

In the case of fascia lata harvest, the IPC device is placed below the woman's patella on the harvest side. The knee is elevated and supported with a 1-L bag of intravenous fluid or an appropriate cushion or pad. The involved extremity is internally rotated at the hip and secured to the table using 3-inch tape, below the operative site. The thigh is prepared and draped to expose its anterolateral aspect from the greater trochanter to the patella distally. The greater trochanter and lateral femoral condyle of the femur are identified and marked. These landmarks denote the proximal and distal attachments of the fascia lata (Dwyer and Kreder, 2008).

Graft Harvest for Autologous Pubovaginal Sling

A 6- to 7-cm Pfannenstiel incision is made approximately 2 cm above the pubic symphysis and carried down to the rectus fascia. A 2-cm × 8-cm graft is then marked out on the rectus fascia in a transverse or longitudinal direction. The premarked graft is harvested using a scalpel or electrocautery (Fig. 125.1A). If a transverse fascial incision is used, maintaining a 2-cm or greater distance away from the pubic symphysis will help ensure a tension-free fascial closure. Freeing the edges of the fascia away from the underlying rectus muscle with a scalpel or electrocautery may also aid in a tension-free closure but could theoretically weaken the fascia. The fascia is closed with a running No. 1 polydioxanone suture (PDS). Alternatively, figure-of-eight 0-0 polyglactin 910 (Vicryl) may be used in women with minimal subcutaneous fat. On the rare occasion the fascia cannot be closed adequately, it may be necessary to place an interposing segment of synthetic mesh or biologic graft.

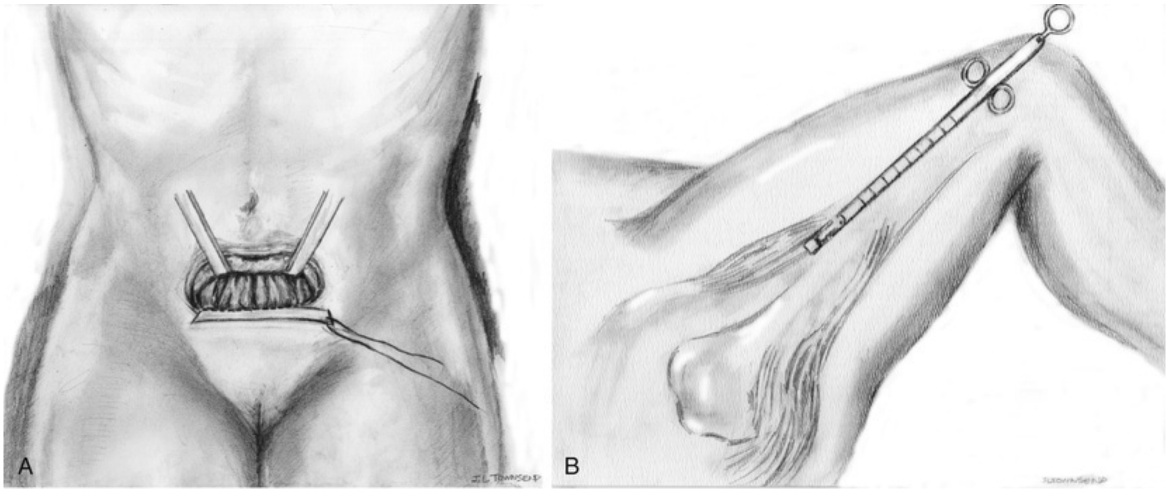

FIG. 125.1 (A) Rectus fascial graft harvest. (B) Autologous fascia lata harvest.

After harvest, the autologous graft is placed in a 0.9% normal saline solution with or without antibiotic. On a sterile side table, the overlying fat and perifascial tissue are cleaned off the graft and a separate No. 1 PDS or 1-0 polypropylene suture is secured to each end of the graft. Each suture should be placed perpendicular to the sling fibers (transverse harvest only), run across each end of the graft, and tied down. Sutures are left long, and the graft is again placed in the saline solution until needed.

For fascia lata harvest, a 3-cm longitudinal incision is marked beginning just above the patella over the iliotibial band (see Fig. 125.1B). Dissection is carried down to the level of the fascia lata, where two parallel, longitudinal, incisions are made 2 cm apart. The graft is bluntly lifted off the underlying muscle and clamped as far distally as possible with a right-angle clamp (3 cm to 4 cm) and transected, allowing one free end. The free end is secured with a No. 1 PDS, and the proximal fascia lata is lifted off the muscle belly with a thin, malleable retractor. The fascia lata is separated from both the adipose tissue and muscle fibers by passing the retractor superficially and deep to the fascia lata. With the free distal end under tension, a Crawford fascial stripper is used to extend the fascial incision proximally and divide it before removal. Classically, a full-length fascial strip (20 cm × 2 cm) was harvested; however, shorter lengths (8 cm) are now commonly used (Karram and Bhatia, 1990). A second No. 1 PDS is secured to the other free end of the graft and the sling is placed in saline until needed. Immediate compression is applied to the thigh to constrict any perforating vessels and the area is carefully evaluated for arterial bleeding before closure. The wound is irrigated and closed in three layers without closing the fascia lata. Once the thigh closure is complete, a compressive wrap is applied to the thigh and the IPC device is replaced. The compressive bandage should remain in place for 8 hours postoperatively and early ambulation should be encouraged (Dwyer and Kreder, 2008).

Pubovaginal Sling Vaginal Dissection

We begin by injecting 0.9% sterile normal saline into the vaginal epithelium corresponding to the mid-urethra and bladder neck to provide hydrodistention and aid in tissue dissection. We prefer an inverted U-shaped incision because it provides excellent exposure of the urethra to the level of the bladder neck and direct access to the endopelvic fascia and subsequently retropubic space (Fig. 125.2). The top of the incision is made approximately 2 cm below the urethral meatus (an Allis clamp placed immediately below the meatus improves visualization and exposure), and the arms of the inverted U-incision should extend to the level of the bladder neck (determined by palpation of the Foley balloon). A 15-blade knife is used to carry this incision down through the vaginal epithelium, with care to stay above the periurethral and pubocervical fascia (to avoid bleeding and injury to the urethra and bladder). Alternatively, a midline vaginal incision extending from the bladder base proximally to the mid-urethra distally can be used. With an Allis clamp and Metzenbaum scissors, thick vaginal epithelial flaps are created. The flaps are retracted with the help of the vaginal ring retractor. It is important to keep the arms of the inverted U-incision wide to avoid devascularizing the flap.

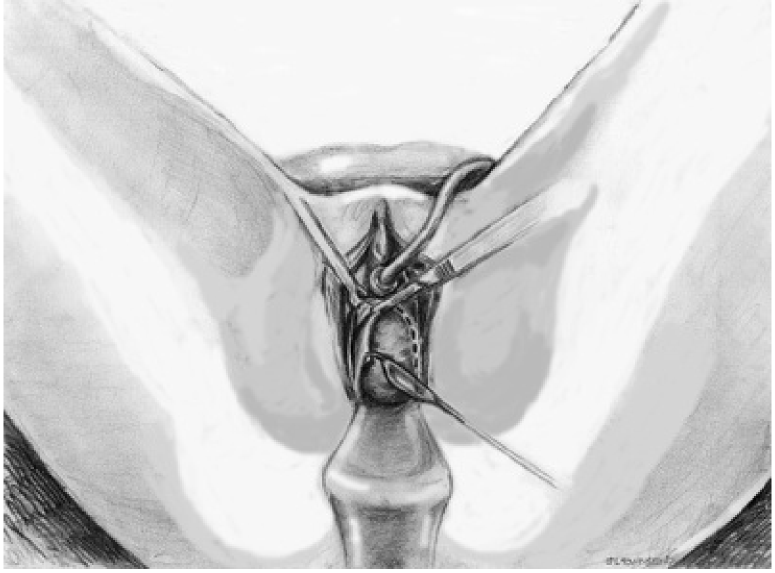

FIG. 125.2 Inverted-U incision.

Once adequate lateral flaps have been created, the endopelvic fascia should now be perforated under the easily palpable ischiopubic rami. To minimize the chance of inadvertent bladder perforation, it is imperative that the bladder be adequately drained before this maneuver and again before the passage of Stamey needles or larger clamps. With the Metzenbaum scissors angled toward the ipsilateral shoulder and the tips pointed upward, the endopelvic fascia is perforated by remaining directly medial and immediately under the ischiopubic ramus at the superior margin of dissection (Fig. 125.3). Perforation occurs in a superolateral direction, and the Metzenbaum scissors are spread widely to aid in the next step of dissection. Using blunt finger dissection, the retropubic space is dissected on either side of the urethra (Fig. 125.4). With this dissection, the infrapubic and retropubic dissection planes are now connected. During this step, it is important to ensure that the retropubic space is fully opened. The posterior surface of the pubic symphysis should be easily palpable with very little intervening tissue. Intraoperatively, this allows for free movement of the sling and easy tensioning.

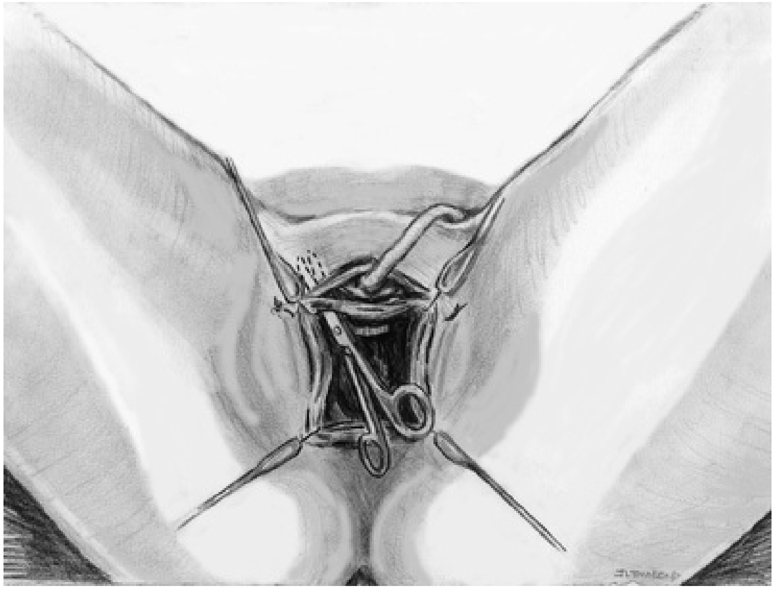

FIG. 125.3 Perforation of endopelvic fascia.

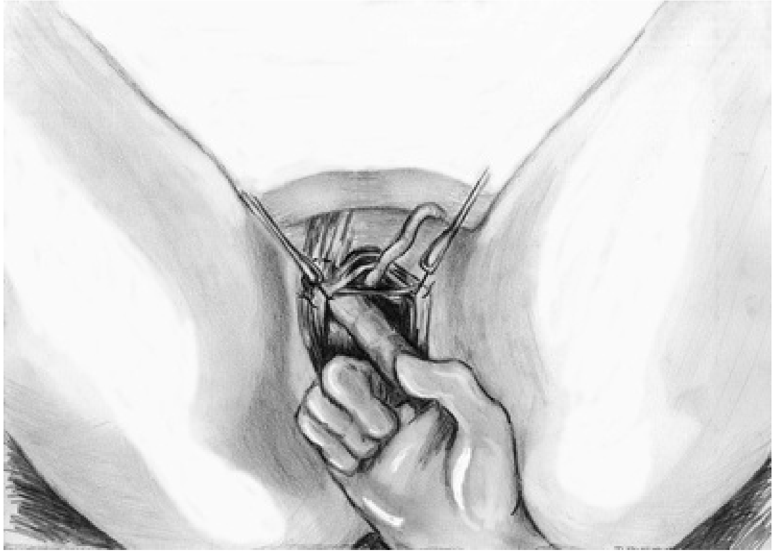

FIG. 125.4 Blunt dissection of retropubic space.

Even though the abdominal fascia is closed, simultaneous finger palpation through the abdominal and vaginal incisions should now be possible, while gently palpating the bladder medially. Aggressive medial mobilization should not be attempted because it may result in bladder injury. Hemostasis should be achieved with bipolar cautery. In the case of women who have undergone prior urethral suspension or sling procedures, more aggressive sharp dissection may be required. In difficult cases, the safest dissection plane into the retropubic space should be immediately adjacent to the periosteum of the pubis, and dissection should be performed sharply as much as possible to minimize the risk for injury to the pelvic viscera.

Pubovaginal Sling Placement and Fixation

Stamey or Cobb-Ragde needles are passed from above, through the abdominal incision by careful guidance behind the pubis. The needles are in contact with the pubis until they are brought out lateral to the bladder into the vaginal incision (Fig. 125.5). Alternatively, larger surgical instruments such as tonsil clamps may also be used for suture advancement (Blaivas and Olsson, 1988; McGuire and Lytton, 1978). **Again, it is important to emphasize that the bladder must be completely drained before passage of any suture passer to avoid inadvertent bladder injury.** Cystoscopy should be performed with a 70-degree lens after passage of needles to confirm integrity of the bladder by following the course of needles while an assistant moves the needles downward and medially toward the bladder. It is our belief that cystoscopy is an essential step that eliminates the serious complication of sling perforation of the bladder. In the case of a small bladder injury or inadvertent passage of Stamey needles through the bladder, the needles are removed and passed again and the procedure is completed. Cystoscopy should be performed after any subsequent needle passage to rule out puncture. After extravesical passage is confirmed, the ureteral orifices are monitored for brisk efflux on each side confirming ureteral patency. Likewise, intravenous methylene blue or sodium fluorescein and ureteral catheters may be used to confirm patency. The Foley catheter is replaced for completion of the case.

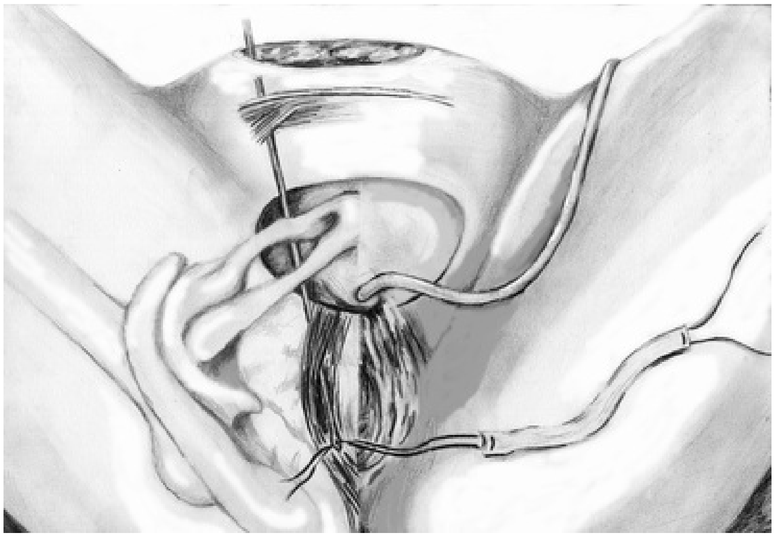

FIG. 125.5 Passage of Stamey needles behind pubis.

The ends of graft suture are passed through the Stamey needle eyelets. After marking the center of the graft with a clamp, the Stamey needles are removed, and the ends of the suture are brought out through the abdominal incision and tagged with hemostat clamps (Fig. 125.6). The distal aspect of the graft is sutured to the periurethral tissue with two simple 4-0 Vicryl sutures. After adequate hemostasis is achieved, the vaginal incision is closed with a watertight, running 2-0 Vicryl suture. **Before final tensioning of the sling, the vagina should be closed and weighted speculum removed to eliminate distortion that can affect the final tension. In addition, any additional procedures, such as transvaginal POP repair, should be completed before sling tensioning.** The PDSs are tied down above the rectus fascia (Fig. 125.7) leaving a two-fingerbreadth width distance between the rectus fascia and the PDS knot. The amount of tension may vary because of the mobility of the urethra or the desire to create permanent retention in a woman who will ultimately perform permanent CIC. The abdominal incision is closed with a subcuticular 4-0 polyglactin 910 suture. The Foley catheter is left to straight drainage, and a vaginal packing may be used. Conjugated estrogen cream may be added to the vaginal packing in postmenopausal women.

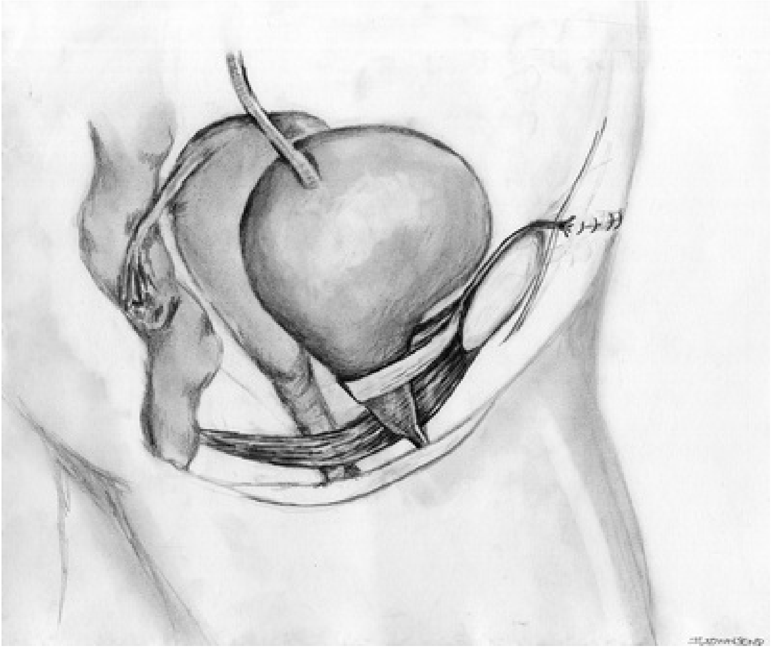

FIG. 125.6 Sagittal view of pubovaginal sling position at bladder neck in retropubic position.

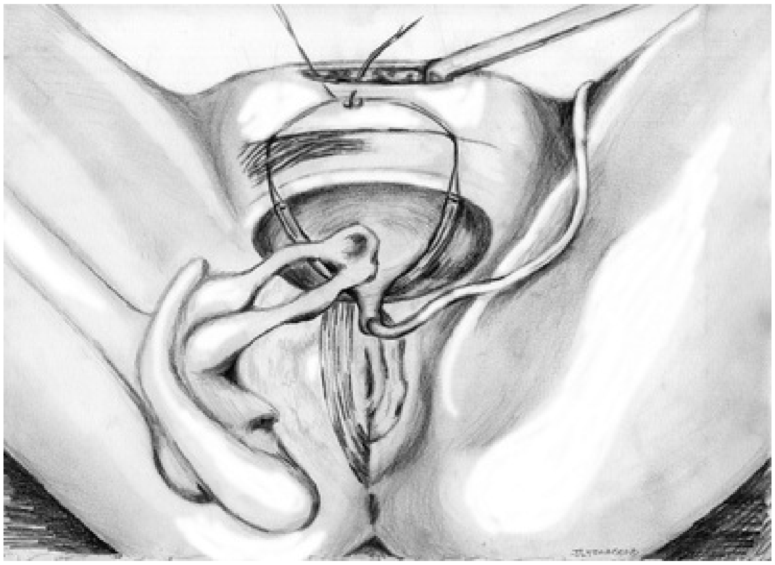

FIG. 125.7 Passage of and tying of sling through abdominal incision.

Pubovaginal Sling Postoperative Care

The patient is allowed liberal fluids and diet the night of surgery and the vaginal packing and urethral catheter are both removed on the morning of the first postoperative day. If the patient voids adequately with low PVR volumes, she is discharged home. If she is unable to urinate or has an elevated PVR volume, she is discharged home with an indwelling Foley catheter and will typically return within 5 days for a repeat trial of voiding. Patients are instructed to avoid lifting in excess of 10 pounds and sexual intercourse for at least 6 weeks after surgery. Sexual intercourse should be resumed only after a physical examination and confirmation of vaginal healing by the surgeon.

Key Points: Pubovaginal Sling Operative Procedure

- On occasion, closure of the rectus fascia without tension may be problematic. To prevent this, it is important to maintain a distance of 2 cm or more from the pubic symphysis.
- If undermining the fascial edges does not adequately mobilize the fascia, interposition of a segment of synthetic mesh or xenograft may be necessary to bridge the gap.
- It is important to ensure that the bladder is empty before perforation of the endopelvic fascia, dissection in the retropubic space, or passage of needles.
- Cystoscopy is recommended after initial trocar passage, and any subsequent passes, to ensure integrity of the bladder and urethra.
- Sling tensioning should be intentionally loose to minimize the chance of obstruction.

Outcomes of Pubovaginal Slings for Predominantly Stress Urinary Incontinence

Autologous Pubovaginal Slings

Since reintroduction in the late 1970s (McGuire and Lytton, 1978), the autologous PVS has remained reproducible and effective in treating SUI in long-term follow-up (Table 125.2). The earliest series included a diverse and complex patient population, including women with pelvic radiation, diabetes, spinal cord injury, and pelvic trauma (Blaivas and Jacobs, 1991; McGuire et al., 1987). Impressively, even the 34% of women with “proximal urethral function loss,” characterized by a MUCP less than 4 cm H_2O, had an 82% cure rate (McGuire et al., 1987). In addition, the majority of the women who required CIC postoperatively had a neurogenic bladder and were counseled to expect urinary retention. Several notable modifications have been described over the years that confirm the versatility of this technique. In a study of 63 women with ISD, Mason and Roach (1996) documented the success of a shorter (4 × 2 cm) modified rectus fascial sling at a mean follow-up of 12 months. Postoperatively, 19% of their population had urgency, and 16% had frank UUI. However, by 6 months, these symptoms had resolved in all but three women (5%), who remained on anticholinergic medication.

TABLE 125.2

Long-Term[a] Outcomes of Autologous Pubovaginal Slings

STUDY	N	TYPE	AGE (MEAN OR MEDIAN YEARS)	GSI	FOLLOW-UP (MEAN OR MEDIAN MONTHS)	CURED, IMPROVED, OR FAILED	ASSESSMENT OF OUTCOME	D U C

CR, Chart review; *FL,* fascia lata; *GSI,* genuine stress urinary incontinence; *NR,* not recorded; *R,* rectus fascia; *UUI,* urgency urinary incontinence; *VD,* voiding diary; *VQ,* validated questionnaire.

Cross et al. (1997) found that a concomitant anterior colporrhaphy and PVS yielded excellent results in women with grade 3 to 4 cystoceles and SUI. In their study, 92% of the 36 cystoceles were considered cured at a median of 20 months after surgery. Thirty-two women (89%) were cured of their SUI based on questionnaire results. While there was a 19% rate of postoperative de novo urgency and UUI, only 3% had persistent UUI requiring treatment. Lastly, 2.8% underwent further urethrolysis to resolve voiding difficulties related to obstruction. In 1998, two groups reported over 90% success rates in greater than 400 women after PVS as measured by questionnaires, telephone interviews, and physician assessment (Chaikin et al., 1998; Cross et al., 1998b).

The modified PVS (MPVS) involves the fixation of a 7- × 2.5-cm graft to the pubocervical and periurethral ligaments in a four-quadrant manner (Ghoniem, 1991). The initial success rate was 95% and, with longer-term follow-up, 89% of 112 women were cured of their SUI (Hassouna and Ghoniem 1999). The latter study assessed outcomes using a quality-of-life (QoL) questionnaire and found the success rate to be lower (81%). All 15 of the women with documented failure had UUI or severe urinary storage symptoms. The additional QoL assessment highlights the impact that UUI, frequency, nocturia, and pain can have on postoperative satisfaction.

A 2001 study by Groutz et al. (2001) involving 67 women is noteworthy because it stratified outcomes based on whether the PVS was for primary (57%) or recurrent SUI (43%). The latter group had undergone one to three prior unsuccessful anti-incontinence procedures, with the rates of transvaginal needle suspension, retropubic suspension, and PVS being 31%, 28%, and 10%, respectively. The cure rate was significantly higher in women with primary SUI (74% vs. 59%, $P = 0.006$); however, all of the women in both groups were either cured or improved based on a combination of 24-hour voiding diary variables, 24-hour pad test, and patient satisfaction.

Providing further evidence that the **PVS is an effective treatment for recurrent SUI,** Richter et al. (2001) assessed long-term QoL in a telephone interview of 57 women who had undergone a PVS. As in the 2001 study by Groutz et al., a significant number of women in this study had recurrent SUI after a failed retropubic (46%) or transvaginal needle suspension (24%). Telephone interviews revealed that 88% of women felt the sling improved their QoL, and 82% stated that they would undergo the surgery again. Remarkably, 87% of women failed their initial postoperative voiding trial, and 12% required long-term CIC. The telephone interviews revealed that 6% of the women had to use adaptive positions to facilitate voiding; however, all of these women were satisfied because of freedom from SUI and did not elect urethrolysis. This satisfaction may be related to an emphasis during preoperative counseling in conveying the possibility of long-term voiding dysfunction after a PVS. Petrou and Frank (2001) also looked at recurrent SUI, but focused on the safety and efficacy of a repeat PVS procedure after failed suburethral slings in 14 women (5 cadaveric bone-anchored slings, 3 autologous PVS, 3 cadaveric bone-anchored PVS, and 3 vaginal patch slings). Overall, 86% considered themselves cured or improved after surgery. Postoperative complications included a pelvic abscess related to a prior cadaveric sling, pubic osteomyelitis related to a prior bone-anchored sling, and one case of long-term urinary retention.

A 2006 study by Howden et al. (2006) is worth noting because of its long (mean of 7.1 years) follow-up and relatively large sample size (153 women). The authors retrospectively assessed outcomes using four different validated questionnaires and found that 72% of women were continent and only 3.3% required reoperation because of SUI within the follow-up period.

Much of the contemporary data regarding autologous PVS are derived from the Stress Incontinence Surgical Treatment Efficacy (SISTEr) trial, a multicenter, randomized clinical trial comparing the rectus fascial PVS in 326 women with Burch colposuspension in 329 women (Albo et al., 2007). The two primary outcomes were resolution of overall urinary incontinence (no subjective incontinence, increase of less than15 g in 24-hour pad weight, and no medical or surgical treatment for incontinence) and resolution of SUI (no subjective SUI and negative stress test). The authors found that, whereas the PVS was more effective at curing SUI (47% vs. 38%, $P < 0.001$), it was associated with a significantly higher rate of postoperative voiding dysfunction and cystitis. Of note, all 20 of the surgical procedures for bladder outlet obstruction (BOO) were performed in the PVS group, and two women in the Burch group experienced intraoperative ureteral injuries. In the long-term observational extension of the SISTEr trial, Brubaker et al. (2012) cited 5-year continence rates of 31% versus 24% ($P = 0.002$) in the PVS and Burch groups, respectively. Satisfaction at 5 years was related to continence status and was higher in the PVS group (83% vs. 73%, $P = 0.04$). While satisfaction decreased with time ($P = 0.001$), it still remained higher in the sling group ($P = 0.03$). The two groups had similar rates of adverse events (Burch 10% vs. PVS 9%) and similar numbers of participants with adverse events (Burch 23 vs. PVS 22). Both studies were especially noteworthy for their prospective, randomized design and seemingly low overall success rates for the PVS, which is most likely related to the strict definition of success and vigilant follow-up regimen. **The disparity between subjective patient outcomes and strict objective cure is another important observation, indicating that postoperative satisfaction is possible even in absence of complete dryness.**

A 2011 study by Athanasopoulos et al. (2011) was one of the earliest and largest studies to describe the outcomes of the PVS in patients in whom MUS had failed. In this study of 264 women, 30% had a prior history of MUS, and all of the women underwent partial sling excision at the time of PVS. The authors reported an 85% overall success rate (markedly improved or cured incontinence) and a history of previous anti-incontinence surgery had no effect on success rates. Additional studies have corroborated their conclusions (see Table 125.2).

Lee et al. (2015) performed a retrospective study with one of the longest follow-up periods after PVS sling surgery. At a median follow-up of 89 months, 63% of 84 women were improved or cured per validated questionnaire. As in earlier studies, the authors found no difference in outcomes between women with previous anti-incontinence surgery and those undergoing primary PVS.

While rectus fascia is the most commonly used autologous material, intermediate-term outcomes of fascia lata PVS appear to be comparable. In a retrospective study of 170 women with recurrent SUI, Beck et al. (1988) noted an impressive 92% cure rate measured by an absence of leakage on a postoperative cough test. It is interesting to note that the authors tested intraoperative urethral pressure to ensure that the slings could create pressures of 80 to 90 cm H_2O. A study by Govier et al. (1997) using fascia lata grafts is noteworthy because the authors compared outcomes of a chart review with responses to a questionnaire and found that the latter yielded poorer, but likely more accurate, outcomes (87.5% vs. 70%, respectively). This patient satisfaction–derived cure rate was similar to the questionnaire-based outcomes noted by Brown and Govier (2000). All of the women in this study had thigh pain at 1 to 2 weeks, and 11% described persistent thigh pain at 6 weeks. Latini et al. (2004) used the Crawford fascial stripper to obtain fascia lata, and, at 1 week, 20% of women had localized numbness at the harvest site, 7% had harvest site pain, and 5% had tendinitis in the harvest site leg. Despite this, 83% of respondents indicated that the procedure had a positive effect on their life, 82% would recommend the surgery to a friend, and 83% would undergo the procedure again. This evaluation remains the only study of fascia lata PVS with a mean follow-up greater than or equal to 48 months.

A Cochrane systematic review of PVS procedures included 26 trials involving 2284 women, most of whom had follow-up periods less than 24 months (Rehman et al., 2017). Twelve of these trials addressed the comparison between PVS and MUS, and the analysis concluded that these procedures were equally effective in the short term (RR for incontinence within first year 0.97, 95% CI 0.78 to 1.20). However, MUS surgery was associated with shorter operating times, fewer perioperative complications (other than bladder perforation) and less postoperative voiding and storage dysfunction. Finally, six trials compared one type of PVS with another, with porcine dermis, lyophilized dura mater, fascia lata, vaginal wall, autologous dermis, and rectus fascia represented. Subjective improvement rates within the first year favored the autologous fascial

PVS over other biologic materials (RR 0.45, 95% CI 0.21 to 0.98).

In summary, **success rates after PVS are typically high, with the wide range of continence rates in the literature (24% to 97%) depending intimately on the study patient population and definition of success.** In general, there is no direct correlation between universally accepted objective and subjective measures of improvement or cure for anti-incontinence procedures (Padmanabhan and Nitti, 2006). The most commonly cited reason for failure relates to other urinary storage symptoms, and UUI at follow-up is a common reason for patient dissatisfaction. **Postoperative de novo or urgency incontinence rates range from 2% to 22%** (Albo et al., 2007; Brubaker et al., 2012; Chaikin et al., 1998; Cross et al., 1998b; Flynn and Yap, 2002; Groutz et al., 2001; Haab et al., 1997; Hassouna and Ghoniem, 1999; Khan et al., 2015; Mason and Roach, 1996; Mitsui et al., 2007; Morgan et al., 2000; Onur et al., 2008; Parker et al., 2016; Zaragoza, 1996).

Allograft Pubovaginal Slings

While the autologous fascial PVS remains the gold standard treatment for SUI because of its efficacy and durability, it is associated with potential harvest site morbidity. Hence, cadaveric allograft slings were introduced in an effort to replicate the tissue integration of an autologous PVS and reduce its harvest site morbidity (Table 125.3). In general**, the outcome data are limited, and the efficacy and durability of these slings are questionable**. Early literature cited frozen or freeze-dried cadaveric fascia lata (CFL) with a variety of methods to secure the sling, such as suture fixation and bone anchors (Almeida et al., 2004; Amundsen et al., 2000b; Brown and Govier, 2000; Carbone et al., 2001; Fitzgerald et al., 1999; Flynn and Yap, 2002; Handa et al., 1996; Howden et al., 2006; O'Reilly and Govier, 2002; Richter et al., 2003; Walsh et al., 2002; Wright et al., 1998). Experience has shown that these tissue-processing techniques can have deleterious effects on cadaveric sling outcomes (Nazemi et al., 2008). **Failure rates for frozen or freeze-dried (FD) grafts range from 6% to 38%, often in the short-term.**

Several groups have commented on the status of cadaveric tissues at reoperation for sling failure. Fitzgerald et al. (1999) cited an early failure rate (within 1 week to 5 months) of 17% in 35 women who underwent irradiated CFL sling. Histopathologic analyses of the retrieved material indicated the following ongoing processes in the failed graft: disorganized remodeling, areas of graft degeneration, and evidence of immune reaction. These findings led the researchers to conclude that freeze-dried, irradiated CFL grafts should not be used for urogynecologic procedures because of the high material failure rate. Since then, additional groups have documented high failure rates with freeze-dried allografts. Carbone et al. (2001) reported a 38% failure rate and a 17% reoperation rate at a follow-up of 11 months after CFL secured with titanium bone anchors to the pubic symphysis. The average time to reoperation was 9 months (range 3 to 15), and intraoperative findings at reoperation revealed the entire allograft to be fragmented, attenuated, or simply absent. O'Reilly and Govier (2002) found that 8 of their 121 patients had recurrent SUI at a mean of 6.5 months (range 4 to 13 months). Seven of the 8 women had multiple comorbidities, including neurologic disease, diabetes, previous pelvic irradiation, and previous anti-incontinence and pelvic surgery. Based on these results and findings by Lemer et al. (1999), this group also discontinued the use of fresh-frozen grafts and switched to solvent-dehydrated cadaveric fascia and dermal grafts.

Graft deterioration and failure has also been reported with solvent-dehydrated CFL and cadaveric dermis (CD). Huang et al. (2001) reported a 28% failure rate with full recurrence of SUI with short-term follow-up. On reoperation with an autologous PVS, the remaining allograft was rudimentary and very friable. Histologic examination of the retrieved allograft revealed wavy collagen fibers with loosely packed fibroblasts and focal areas of degeneration. Owens and Winters (2004) observed promising initial results in women treated with CD slings with dry and improved rates of 68% and 24%, respectively. However, at intermediate follow-up, only 32% of the women were dry, and 36% noted improvement. Surgical re-exploration revealed almost complete absence of graft material, without evidence of infection or excessive inflammatory response.

Six studies have compared the outcomes of women undergoing PVS procedures using either autologous or cadaveric allograft fascia (Almeida et al., 2004; Brown and Govier, 2000; Flynn and Yap, 2002; Howden et al., 2006; Onur et al., 2008; Wright et al., 1998). Four groups found the outcomes comparable with similarly high success rates and no negligible difference in complications. They concluded that allograft fascia lata may be used as an alternative to autologous fascia for PVS to reduce operative time and decrease postoperative pain and disability (Brown and Govier, 2000; Flynn and Yap, 2002; Onur et al., 2008; Wright et al., 1998). With long-term follow-up, two groups noted superior continence outcomes in the autologous group (Almeida et al., 2004; Howden et al., 2006). Almeida et al. (2004) did not report adverse outcomes in either group, and Howden et al. (2006) found that recurrent symptoms occurred in a higher proportion in the cadaveric group (40%) compared with the autologous group (28%) (*P* = 0.04). The reoperation rate was also higher for the allograft group (13% vs. 3%, *P* = 0.003). As mentioned in the previous section, the subjective improvement rates within the first year favor autologous fascial PVS over other biologic materials in the systematic review of randomized controlled trials (RCTs) by Rehman et al. (2017).

Some studies support the efficacy of solvent-dehydrated fascial slings (Frederick and Leach, 2005; Nazemi et al., 2008; Onur and Singla, 2005; Pianezza et al., 2007), yet previously reported failures coupled with the consistent success and rapid adoption of synthetic MUS have led to near-complete abandonment of all types of cadaveric allografts at most centers. Hence, there is an almost complete absence of long-term outcomes for solvent-dehydrated allograft slings (Nazemi et al., 2008).

Synthetic Pubovaginal Slings

Although there were multiple single-center, retrospective studies describing synthetic PVS placed at the bladder neck, there are few randomized studies evaluating outcomes. One of those studies is a prospective, randomized trial comparing the ePTFE PVS with the Burch colposuspension (Sand et al., 2000). Seventeen women were randomized to sling, and the authors concluded that the synthetic suburethral sling had equivalent results to the modified Burch procedure after 3 months of follow-up. It is interesting to note that, although the authors reported no problems with exposure or perforation, they state in their discussion section that they stopped using this type of sling because of complications reported in 1995 by Weinberger and Ostergard. In that study, 108 women were treated with an ePTFE PVS for SUI. Forty percent developed a wound complication and 21% required complete or partial sling removal (10 with sinus tract formation, 4 with persistent vaginal granulation, 3 with prosthetic exposure, and 1 with groin pain). Clearly ePTFE is not an ideal synthetic sling material because of its microporous nature. Likewise, there have also been problems with other synthetic sling materials (polyethylene and polypropylene) with less-than-ideal physical properties placed under tension at the bladder neck (Drutz et al., 1990; Wohlrab et al., 2009; Young et al., 2001).

Xenograft Pubovaginal Slings

Xenografts represented an attractive surgical option because of the morbidity of autologous fascial harvest, high failure rates of allografts, and high exposure and perforation rates after synthetic PVS. **In general, xenografts are associated with a low rate of infection, exposure, and perforation because of their incorporation into host tissue** (Rutner et al., 2003). The majority of studies in the literature report on gamma-sterilized, porcine dermis (Pelvicol, C.R. Bard), porcine small-intestinal submucosa (SIS), and bovine dermis for use in PVS surgery (Abdel-Fattah et al., 2004; Arunkalaivanan and Barrington, 2003; Barrington et al., 2002; Broussard et al., 2013; Giri et al., 2006; Holstead et al., 2013; Khan et al., 2015; Rutner et al., 2003; Wiedemann and Otto, 2004; Wilson et al., 2008) (Table 125.4).

TABLE 125.4

Outcomes With Xenograft Pubovaginal Slings

STUDY	N	TYPE	AGE	FOLLOW-UP (MONTHS)	CURED, IMPROVED, OR FAILED	ASSESSMENT OF OUTCOME	DE NO URGE
Barrington et al., 2002	40	Pelvicol	56	6–18	85%	Subjective improvement >90%	NR

Holstead et al., 2013	41	Xenform Matrix[a]	67.6	36	81% SUI cure	Stress test; VQ	2.4%
Khan et al., 2015	38	Pelvicol	62	120 (median)	15.7% dry, 58% improved	Subjective; VQ	0%

[a] Xenform Matrix is an acellular bovine dermis.

CR, Chart review; *NR,* not recorded; *SIS,* small intestinal submucosa; *SUI,* stress urinary incontinence; *VQ,* validated questionnaire.

Rutner et al. (2003) were first to describe the bone-anchored porcine SIS in 152 women with long-term follow-up and reported cure rates comparable to those of the autologous PVS. Among the 7 failures (5%), 5 women had recurrent SUI within 3 months of surgery, and the other 2 had recurrences after 9 and 11 months. At reoperation, grossly no evidence of the implanted SIS material was found; however, biopsies of the periurethral tissue did reveal fibrosis and muscular tissue with a few remnants of SIS. Wiedemann and Otto (2004) performed the first extensive histopathologic examination of porcine SIS in a series of 15 women. Biopsy specimens from the SIS band under the vaginal mucosa revealed only focal residues of SIS without any evidence of tissue reaction. Evidence of a significant immunologic or chronic inflammatory reaction was absent. These authors concluded that the advanced incorporation of the implant would lend to good biocompatibility.

Arunkalaivanan and Barrington (2003) first reported on Pelvicol PVS in a randomized, short-term trial comparing the xenograft with TVT. Questionnaire-based cure rates were comparable between the two: 85% in the TVT group and 89% in the Pelvicol group. Abdel-Fattah et al. (2004) presented 3-year follow-up data for this prospective trial, and cure rates remained high and comparable between the two groups: 79% for the TVT and 78% for Pelvicol. There was no statistical difference with regard to complication rates or postoperative pad score. Giri et al. (2006) compared the 3-year efficacy of Pelvicol versus autologous PVS in 101 consecutive, nonrandomized patients, and, although there was less surgical morbidity in the porcine dermis group, long-term cure rates were significantly lower than for the autologous PVS group. Repeat urodynamic studies indicated recurrent SUI as the cause of treatment failure in 18 of 20 (90%) patients treated with porcine dermis but in only 3 of 8 (37.5%) with a rectus PVS.

Bovine dermis is the most recently reported material used for a xenograft PVS (Wilson et al., 2008). Women with a high risk for sling failure (advanced age, previous surgical failure, and ISD) underwent either a bovine dermis or autologous rectus fascia PVS procedure with short-term follow-up. Global cure rates (completely dry and satisfied) and SUI cure rates were not statistically different between the two groups. Four women (8%) in the autologous PVS group underwent reoperation with periurethral bulking and repeat autologous PVS. Two women (5%) in the bovine dermis group underwent additional interventions with periurethral bulking and an autologous PVS. Biopsies of the bovine dermis sling material during reoperation (for SUI recurrence at 3 months) revealed that the sling had been replaced by fibrosis, hemorrhage, and mild chronic inflammatory infiltrate, with no acellular component. Tissue breakdown, represented by intermittent areas of myxoid degeneration, was present and may have indicated evidence of early graft failure. The same group reported an SUI cure rate of 80.5% and a low complication rate at a minimum follow-up of 36 months (Holstead et al., 2013).

Outcomes of Autologous Pubovaginal Slings for Mixed Urinary Incontinence

The treatment of women with SUI and concomitant urgency and UUI is complicated and often involves a combination of anticholinergic therapy and surgery. Medical therapy for MUI is associated with significant resolution of the urgency component in only two-thirds of patients (Nordling et al., 1979; Stephenson and Mundy, 1994). Anticholinergic therapy alone does not address the bladder outlet and would not be expected to achieve complete dryness in those with a significant stress component. **However, anti-incontinence surgery may cure, improve, or aggravate storage symptoms. Furthermore, even an "uncomplicated" sling may lead to de novo urgency. This aspect of anti-incontinence surgery is unpredictable and a major cause of patient dissatisfaction.**

Fulford et al. (1999) were the first group to use video-urodynamics in assessing the impact of a PVS on MUI. In this study, 69% of 85 women had MUI. Although 97% of the women were continent, only 78% were satisfied with the surgical result because of persistent or de novo urgency symptoms. Among these 27 women, 41% had an open bladder neck at rest compared with only 8% of those without postoperative UUI ($P < 0.01$). The storage symptoms eventually resolved in 69% of the women, almost all of whom had a closed bladder neck at rest. Of note, the **postoperative urgency symptoms were not significantly associated with any preoperative clinical or urodynamic variables.**

Schrepferman et al. (2000) tried to use preoperative video-urodynamics to predict urinary urgency resolution after a PVS procedure. Women with MUI were divided into two groups: a sensory urgency group (28 women without DO) and a motor urgency group (41 women with DO). The authors concluded that there was a significantly greater resolution of urgency symptoms in those women with low-pressure DO than in those with high-pressure DO or no DO. Overall, urgency resolved in 51% of women with MUI. Also in 2000, Serels et al. reviewed the records of 36 women with stress-induced DO. In this study, 75% of women had resolution of UUI, and 92% achieved a cure. Again, ALPPs measured during urodynamic studies did not correlate with outcomes.

Osman (2003) compared the outcomes of PVS and Burch colposuspension in women with MUI without DO and a control group of women with SUI. The

Burch arm consisted of 24 women (8 SUI, 16 MUI) with an ALPP greater than 90 cm H_2O, and the PVS arm consisted of 26 women (12 SUI, 14 MUI) with an ALPP less than 90 cm H_2O. In the PVS group, the incidence of persistent UUI in the MUI group was 12%, and the incidence of de novo UUI in the SUI group was 20%. The incidence of residual urgency was not significantly higher than that of de novo urgency in those with SUI.

Chou et al. (2003) used a validated questionnaire, voiding diary, and pad testing to report the outcomes of PVS for MUI and SUI. Forty-seven percent of 98 women had SUI, and 53% had MUI (26% with DO). The cure or improvement rates were 97% in the SUI group and 93% in the MUI group ($P = 0.33$). More urgency and UUI episodes on preoperative voiding diary correlated directly with surgical failure, whereas voiding frequency was associated with cure. The authors postulated that these women may have adopted preemptive voiding preoperatively to minimize incontinence episodes.

Stoffel et al. (2008) found no difference in preoperative video-urodynamics between women with MUI and DO and those without DO. However, MUI patients with DO had less improvement in UDI-6 scores than those without DO despite a similar reduction in pad use. The authors concluded that the presence of preoperative DO on urodynamic findings may relate to decreased QoL and decreased urgency resolution after a PVS.

To date, women with MUI have no consistent video-urodynamic parameters that correlate with outcomes after a PVS. **However, the presence of residual urgency is similar to de novo urgency after a PVS. Also, increasing episodes of urgency and UUI may correlate with surgical failure. Overall, the PVS remains an effective treatment option for women with MUI, with cure rates similar to those of women with SUI only.**

Outcomes of Autologous Pubovaginal Slings for Urethral Reconstruction

An autologous PVS serves an important role in the reconstruction of the urethra after anatomic damage (tissue loss) ranging from the relatively mild deformity of urethrovaginal fistulae and diverticula to the more severe, traumatic absence of the urethra or bladder neck. Causes of damage may also include protracted obstetric deliveries, anti-incontinence surgeries, aggressive transurethral resections of the bladder neck, long-term indwelling urethral catheters, pelvic trauma, tumors, and radiation (Blaivas and Jacobs, 1991). The goals of surgical repair are to restore function and anatomy while fashioning an unobstructed, continent urethra (Blaivas and Heritz, 1996).

Swierzewski and McGuire (1993) reviewed the outcomes of 14 women who underwent urethral diverticulectomy during a 3-year period, 8 of whom had preoperative symptoms of SUI. Seven of these women had SUI documented on preoperative urodynamic studies, and only these seven women underwent a combined urethral diverticulectomy and autologous PVS. All 14 women were cured of their SUI with a mean follow-up of 17 months (3 to 21 months). The authors concluded that the presence of a urethral diverticulum does not compromise the successful cure of SUI by a PVS.

Chancellor et al. (1994) performed obstructing PVS in 14 women with neurogenic bladder dysfunction who had destroyed urethras secondary to long-term, indwelling Foley catheters. Ten women had simultaneous bladder augmentations or diversions, and two had concurrent suprapubic tube placement. The other two had adequate preoperative bladder capacity and compliance. All women achieved continence after a mean follow-up of 24 months. The authors concluded that obstructing PVS is simpler and avoids the risk for fistula formation associated with bladder neck closure, which has historically been used in the aforementioned patient population.

Blaivas and Heritz (1996) reported on 49 women who underwent a one-stage urethral reconstruction to repair extensive damage to the urethra or bladder neck (45% from prior urethral diverticulectomy). Forty-one of these women had a concomitant PVS placed for preoperative SUI. At a mean follow-up of 4 years after PVS, none had postoperative SUI, and only one woman experienced obstruction and urgency symptoms requiring sling incision. She was continent at last follow-up. On the other hand, three of the five women who had modified Pereyra suspensions developed postoperative SUI requiring staged PVS. All three were continent at last follow-up. **This study illustrates that PVS in the setting of urethral reconstruction has excellent results when compared with other anti-incontinence surgeries.**

Faerber (1998) reported on 16 women who underwent urodynamic evaluation before simultaneous PVS and diverticulectomy. All were either significantly improved (12%) or cured (88%) of incontinence, and only two patients developed de novo urgency. A Foley catheter was left in place for urethral healing for the initial 2 weeks, and the mean time for complete bladder emptying was 5 weeks.

Rovner and Wein (2003) reported on 9 women undergoing circumferential urethral diverticulum repair who received either end-to-end urethroplasties or dorsal urethroplasties. Based on preoperative SUI status or evidence of an open bladder neck on preoperative cystography, seven women underwent concurrent rectus fascial PVS and one had a porcine PVS. All women were continent postoperatively, except for the one who refused PVS surgery and developed de novo SUI.

Flisser and Blaivas (2003) evaluated the results of 74 women with urethral pathology who required vaginal flap reconstructions, mostly for a diverticulum or urethral fistula secondary to iatrogenic causes. Fifty-six underwent a concomitant PVS, and 73% considered themselves cured postoperatively. Three of the four women with persistent SUI failed a modified Pereyra procedure, but were cured at reoperation. One woman was continent after operative revision of PVS for obstruction and significant UUI.

More recently, autologous PVS have been employed for urethral reconstruction in the setting of MUS urethral perforation. In a retrospective review of 19 women, Kowalik et al. (2018) treated seven with a concomitant ARF PVS. Although 54% rated their postoperative condition as “very much better” or “much better” on the PGI-I at a mean of 25 months of follow-up, much of the cohort required adjunctive measures to treat their persistent urinary tract symptoms.

Key Points: Pubovaginal Sling Outcomes

- Cure rates after autologous PVS range from 31% to 97% depending on the definition of success and outcomes measured. De novo urgency and UUI rates are likewise variable.

- No preoperative risk factors consistently predict outcomes after a PVS.
- The reported cure rate of PVS surgery for recurrent SUI is excellent. In randomized trials, porcine dermis was associated with significantly inferior long-term cure rates compared with the autologous PVS.
- Treatment of women with MUI is complicated and may involve a combination of anticholinergic therapy and surgery.
- The PVS is an effective treatment option for stress-induced DO, with cure rates similar to those of PVS for SUI. The presence of preoperative DO may be associated with decreased postoperative QoL and lower urgency resolution rates after a PVS.
- An autologous PVS is a valuable adjunct for providing continence and robust tissue coverage in urethral reconstruction caused by urethral fistula, diverticulum, urethral perforation after MUS, or devastated urethra.

Voiding Dysfunction Secondary to Bladder Outlet Obstruction After Pubovaginal Sling Surgery

Depending on the definition, the incidence of voiding dysfunction after PVS surgery varies widely (2.5% to 35%) (Carr and Webster, 1997; Chaliha and Stanton, 1999; Cross et al., 1998b; Foster and McGuire, 1993), and iatrogenic bladder outlet obstruction after PVS may be related to DO and impaired detrusor contractility. Morgan et al. (2000) reported a prolonged urinary retention rate of only 2.4% of 252 women at 4-year follow-up. A meta-analysis by the AUA Stress Urinary Incontinence Clinical Guidelines Panel reported that the incidence of urinary retention more than 4 weeks after PVS placement was 8%, and the risk for permanent retention “generally does not exceed 5%” (Leach et al., 1997). It must be noted that the most recent AUA SUI guidelines panel did not note this (Kobashi et al., 2017). Overall, the rate of retention is approximately 2% unless the sling is purposefully overtensioned.

The PVS is known to be associated with higher rates of voiding dysfunction than the Burch colposuspension (Stanton et al., 1983), and this finding was again confirmed in the randomized SISTEr trial (Albo et al., 2007). Success rates were higher for women who underwent the autologous PVS compared with the Burch, but women undergoing PVS experienced significantly greater postoperative voiding dysfunction (63% vs. 47%, $P < 0.001$), UTIs, difficulty voiding, and postoperative UUI.

The presentation of a woman with postoperative bladder outlet obstruction may be quite variable. She may have purely voiding symptoms (e.g., decreased force of stream, positional emptying, elevated PVR volume, and urinary retention), storage symptoms (urgency, UUI), or a combination of both. Obstruction may also cause recurrent UTIs, prolonged suprapubic pain, and painful voiding, even if emptying is completed and PVR volumes are low. Nitti et al. (2002) found that 16% of women who required urethrolysis after PVS did not have voiding symptoms or retention. Some studies report that persistent postoperative UUI and urgency after PVS constitute a more common presentation for obstruction than frank retention (8% vs. 25%) (Cross et al., 1998b). The risk for iatrogenic obstruction is usually related to technical factors such as placement of sutures or sling material under excessive tension. Unfortunately, there is often a fine line between inadequate and excessive sling tension and no consistent way of determining perfect tension for the individual woman. If the sling is too loose, the bladder neck and proximal urethra are inadequately supported and the potential for persistent SUI is greater. Conversely, there may be excessive elevation of the bladder neck toward the pubic bone, causing hypersuspension or overcorrection of the urethrovesical angle and increasing the potential for obstruction.

Not surprisingly, the presence of preoperative voiding dysfunction affects a woman's ability to empty after anti-incontinence surgery. Subclinical impaired detrusor contractility may manifest symptomatically with a relative obstruction when bladder outlet resistance is increased after anti-incontinence surgery. Dysfunctional voiding, or failure of relaxation of the external (striated) urethral sphincter, may also affect emptying after surgery (FitzGerald and Brubaker, 2001). Likewise, a woman who habitually voids by abdominal straining may theoretically have difficulty emptying postoperatively, as the sling provides dynamic resistance with increases in intra-abdominal pressure. Because of the variability of presenting symptoms after PVS surgery, a thorough history is invaluable in ascertaining the chronology, character, and bother of the predominant symptoms.

If a woman has postoperative urethral obstruction, physical examination may reveal abnormal urethral angulation, a foreshortened nonpliable vagina, or a nonmobile urethra. However, hypersuspension may not be clearly evident on physical examination. The PVR volume is very important in the evaluation of voiding dysfunction, although no clear cutoff values for obstruction exist (Siddighi and Karram, 2007). Cystoscopy is useful to rule out bladder pathology, sling perforation, and a hypersuspended urethra. Video-urodynamics may be useful in selected cases at the physician's discretion; however, a classic high-pressure, low-flow pattern that is pathognomonic for obstruction is frequently absent. **The temporal relationship between the onset of voiding or storage symptoms and the surgical procedure remains the most important criterion influencing the decision to incise a PVS or perform urethrolysis.**

Several studies have attempted to identify risk factors that may be predictive of postoperative voiding dysfunction. Weinberger and Ostergard (1996) studied 108 women receiving synthetic PVS and found that impaired detrusor contractility predicted postoperative urinary retention. Similarly, Miller et al. (2003) noted that women who underwent allograft PVS and voided with minimal or no increase in detrusor pressure (19%) had a significantly higher risk for postoperative retention. In contrast, no woman with a normal detrusor contraction developed retention postoperatively. However, other researchers have not confirmed this proposed association (McLennan et al., 1998). Mitsui et al. (2007) found that women with a PVR greater than 100 mL ($P = 0.05$) or Qmax less than or equal to 20 mL/sec ($P = 0.09$) on preoperative urodynamic studies were more likely to require prolonged CIC after surgery. In this group, 28% needed CIC for 4 to 40 months. In the SISTEr trial, urodynamic findings did not predict voiding dysfunction after surgery (Lemack et al., 2008). **Although urodynamic studies are useful in understanding the voiding dynamics of incontinent women, low detrusor pressure and Valsalva voiding preoperatively should not exclude women from having an anti-incontinence procedure.**

In general, although postoperative urgency and UUI (voiding dysfunction) are strongly related to failure, there are few preoperative risk factors that consistently predict these outcomes after PVS surgery. What is known is that preoperative DO on urodynamics (Alperin et al., 2008), high-pressure DO (Schrepferman et al., 2000), preexisting urgency, frequency, and nocturia (Alperin et al., 2008; Gamble et al., 2008; Kenton et al., 2009), and preoperative anticholinergic use (Barber et al., 2008; Kenton et al., 2009) have all been found to be independent predictors of postoperative urgency and UUI. These findings underscore the importance of preoperative counseling and obtaining a detailed history of all storage symptoms before sling surgery.

A key factor in assessing voiding dysfunction is the presence of POP that was either uncorrected at time of surgery or that occurred postoperatively. Prolapse of sufficient size may kink, angulate, or externally compress the urethra causing obstruction, and postoperative POP in all three compartments (apical, anterior, and posterior) must be ruled out as a cause of obstruction. Kobashi et al. (2002) reported on a technique of combined cystocele repair and PVS using a single piece of cadaveric fascia in 132 women. At a mean follow-up of 12 months, only one woman developed persistent obstruction that required urethrolysis. Barnes et al. (2002) reported on 38 women with grade 3 or 4 POP and occult SUI who underwent concurrent PVS with prolapse repair. No woman developed permanent urinary retention, and two developed de novo UUI. Preoperative UUI resolved in 45%. The authors concluded that concurrent surgery had little negative effect on postoperative bladder emptying. In general, there is a paucity of literature on the effects of concurrent PVS and prolapse repair on postoperative emptying and voiding symptoms.

Surgical Management of Voiding Dysfunction After Pubovaginal Sling Surgery

Although transient urinary retention is common, most women return to spontaneous and efficient voiding within the first 10 days (Cross et al., 1998b; Zaragoza, 1996). Obstruction after an autologous PVS usually improves or resolves with time, and, for this reason, most clinicians historically wait up to 3 months before considering surgical intervention. Obstruction after MUS is different and will be discussed later in this chapter. **It is appropriate to initially treat persistent postoperative voiding dysfunction conservatively.** This includes temporary indwelling catheter drainage, CIC, timed voiding, double voiding, biofeedback, PFMT, and anticholinergic therapy.

If the woman is in complete retention, sling revision may be undertaken sooner. In the first 6 weeks after autologous PVS, there may be success with loosening the sling in the operating room using spinal or general anesthesia. This is performed by inserting a cystoscope into the bladder and then gently applying inferior pressure to the urethra; **however, this procedure is not advised with synthetic slings.** Other anecdotal evidence also shows improvement in obstruction with urethral dilation and downward traction after autologous PVS; however, results may range from temporary relief to worsening of the urethral rigidity secondary to periurethral fibrosis (Beck et al., 1988; Zimmern et al., 1987). Transurethral resection or incision of the bladder neck is likely to fail because the sling is extraluminal, and transurethral resection may damage the sphincter or bladder neck or cause periurethral fibrosis, leading to worsened incontinence or a bladder neck contracture (Ghoniem and Elgamasy, 1995). After 6 weeks, or when conservative measures fail, sling incision or a formal urethrolysis is indicated.

Surgical management of bladder outlet obstruction after a PVS has traditionally involved complete urethrolysis by a retropubic, transvaginal, or suprameatal approach, with success rates ranging from 65% to 93% (Carr and Webster, 1997; Cross et al., 1998a; Goldman et al., 1999; Foster and McGuire, 1993; Petrou et al., 1999). Most of these series include women with obstruction after different anti-incontinence procedures, and only two groups stratified their results specifically for PVS (Foster and McGuire, 1993; Petrou et al., 1999). Foster and McGuire (1993) reported that transvaginal urethrolysis was successful in 50% of obstructions from PVS, which was lower than that for both needle suspensions (75%) and retropubic urethropexy (63%). Their conclusion was that transvaginal lateral dissection is insufficient in relieving the direct suburethral compressive force of the sling. Petrou et al. (1999) concluded that the suprameatal approach is superior to the transvaginal approach because the former allows access and division of the lateral wings of the sling. In their series, 8 of 12 women had successful results. In another series of 12 women, Petrou and Young (2002) reported resolution of obstruction in 10 women after retropubic urethrolysis. Of note, 2 of these 10 women subsequently developed SUI. Carr and Webster (1997) reported significant or complete resolution of symptoms in 86% of women after retropubic urethrolysis. Overall, recurrent SUI after formal urethrolysis is reported to range from 0% to 19% (Table 125.5).

TABLE 125.5

Result of Therapy for Bladder Outlet Obstruction After Pubovaginal Sling Surgery

---

STUDY	N	MANAGEMENT	MEAN TIME TO TREATMENT (MONTHS)	SUCCESS RATE	RECURRENT SUI	S T
Foster and McGuire, 1993	10	Transvaginal urethrolysis	25.9	50%	0%	N
Carr and Webster, 1997	51	Retropubic, vaginal, or infrapubic urethrolysis	15	Retropubic, 86% Vaginal, 73% Infrapubic, 25%	13.7%	N
Cross et al., 1998a	15	Transvaginal urethrolysis	16	72%	6.7%	F
Goldman et al., 1999	11	Transvaginal urethrolysis	14	84%	19%	N
Petrou et al., 1999	12	Suprameatal transvaginal urethrolysis	18	66.7%	0%	N
Defreitas and Herschorn,	16	Lateral sling lysis	NR	94%	34%	N

2000						
Amundsen et al., 2000a	32	Transvaginal urethrolysis, 22 Sling lysis, 10	9.8	84%	12.5%	C
Kusuda, 2001	5	Sling lysis	1.5–24	100%	0%	N
Nitti et al., 2002	19	Sling lysis	10.6	84%	17%	
Goldman, 2003	14	Sling lysis	8.6	93%	21%	M
Scarpero et al., 2003	24	Repeat transvaginal urethrolysis (23), retropubic urethrolysis (1)	9	92%	18%	C
Thiel et al., 2005a	13	Sling lysis	2.2	45% cured 45% improved	7.7%	N

MUS, Mid-urethral sling; *NR,* not recorded; *PVS,* pubovaginal sling; *SUI,* stress urinary incontinence.

Sling incision is associated with comparable success rates (84% to 100%), shorter operative time, and less morbidity than formal urethrolysis (Amundsen et al., 2000a; Goldman, 2003; Kusuda, 2001; McLennan and Bent, 1997; Nitti et al., 2002; Shenassa et al., 2000; Thiel et al., 2005a). Most series report the outcomes of a single midline PVS incision; however, incision of the sling in conjunction with the interposition of autologous graft between the cut ends of the sling has been described to successfully prevent recurrent SUI (Ghoniem and Elgamasy, 1995). Others, however, have found that this technique does not live up to expectations. Shenassa et al. (2000) and McLennan and Bent (1997) used vaginal wall interposition in 12 and 4 women, respectively. Successful relief of obstruction was achieved in 92% and 100%, respectively, but SUI recurred in 25% of women in each series.

Several authors have reported on successful midline or lateral sling incision without graft interposition. Defreitas and Herschorn (2000) had a 94% success rate in 16 women after lateral sling incision, with a 34% rate of recurrent SUI Kusuda (2001) reported successful outcomes in five women who underwent a similar procedure. A lateral incision theoretically minimizes the chance of urethral injury in those cases when the sling is identified, but the dissection plane between the urethra and sling cannot be established safely. Amundsen et al. (2000a) used a midline PVS incision in 10 of 32 women in whom the sling was easily identified and a formal transvaginal urethrolysis with entrance into the retropubic space in the remainder. The overall success rate was 84%, but the results were not stratified between sling incision and formal urethrolysis. Of note, in 9 of the 12 women with obstructing autologous slings, the sling material could not be identified and was replaced by dense fibrosis. Nitti et al. (2002) reported on 19 women who underwent PVS incision and cited an 84% success rate with a 17% rate of recurrent SUI. Two of the three women with urethrolysis failure underwent subsequent successful retropubic urethrolysis, which allowed for complete release of all retropubic scarring, which likely contributed to the initial failure of sling incision. Goldman (2003) performed simple sling incision in 14 women with iatrogenic urethral obstruction, three of whom had a MUS. Ninety-three percent had complete or significant improvement of voiding dysfunction, and one woman required subsequent formal urethrolysis. Three women (21%) developed recurrent SUI; however, only one required treatment with a repeat MUS. Thiel et al. (2005a) reported long-term results after simple sling incision for 13 women with catheter-dependent urinary retention after PVS. At 5 years of follow-up, 45% of women reported cure, and 45% were improved. Eight percent noted recurrent SUI but chose not to pursue further therapy.

There are no preoperative or urodynamic parameters that consistently predict success or failure of urethrolysis. Foster and McGuire (1993) found that women with DO had a higher rate of failure, but later studies contradicted this. Carr and Webster (1997) found that the only parameter predictive of success was no prior urethrolysis, and Nitti and Raz (1994) found that failure was related to higher PVR volume; however, these factors have not been confirmed by others.

Persistence of storage or voiding symptoms after urethrolysis may be caused by persistent or recurrent obstruction, DO, impaired detrusor contractility, or learned voiding dysfunction. Recurrent obstruction may result from periurethral fibrosis and scarring or intrinsic damage to the urethra that has occurred from previous urethrolyses. The most common reason for failure is likely insufficient dissection and lysis of the urethra. Scarpero et al. (2003) found that repeat urethrolysis after initial failure resolved obstruction in 92% of 24 women. Both transvaginal and retropubic approaches were employed depending on the clinical situation. Storage symptoms resolved in only 12%, and, even though improvement was often observed, 69% continued to require anticholinergic therapy. SUI recurred in 18% of the women. This supports the use of repeat urethrolysis in the face of initial failure, or in cases in which the aggressiveness of the initial dissection is in question. Finally, a retropubic urethrolysis may also be considered after an aggressive transvaginal urethrolysis has failed.

Refractory urinary storage symptoms after urethrolysis (>50%) affect patient satisfaction and QoL and constitute a treatment challenge (Starkman et al., 2008a). There are no predictors of this outcome after urethrolysis, yet preoperative DO may suggest an increased likelihood of refractory OAB. Likewise, there are no established guidelines for optimal management. Starkman et al. (2007) evaluated 25 women with UUI after pelvic surgery (19 PVS, 3 retropubic suspension, and 3 transperitoneal vesicovaginal fistula repair) of whom 4 required further urethrolysis. The authors found that 80% of the women reported greater than 50% improvement in their symptoms, and 6 were continent after subsequent sacral neuromodulation (SNM). There were no significant differences in response based on age, duration of symptoms, type of surgery, and urodynamic parameters. One year later, Starkman et al. (2008b) evaluated the value of SNM in the management of 8 women who had undergone at least one urethrolysis. Six women had a favorable response during test stimulation, and all six remained significantly improved after implantation of an implantable pulse generator. Hence, in addition to anticholinergics, SNM should be considered as an option for de novo or refractory urgency and urgency incontinence after urethrolysis.

With FDA approval of onabotulinumtoxinA for both idiopathic and neurogenic DO, this modality has also been employed for treatment of persistent and de novo OAB symptoms after sling surgery. Miotla et al. (2016) prospectively enrolled 53 women with idiopathic and 49 with de novo OAB symptoms after MUS and administered 100 Units of onabotulinumtoxinA. At 12 weeks, 41.5% of the women in the idiopathic group and 38.8% in the de novo group were completely dry. In both groups, there was a significant improvement ($P < 0.001$) in the daily number of voids (–2.39 and –2.0) and incontinence episodes (–1.38 and –1.44), with no significant difference between groups. Mean voided volume increased by >90 mL in both groups, and urinary retention was observed in four women. It must be noted that these women did not undergo sling revision first, and there are no studies specific for intravesical injection of onabotulinumtoxinA for persistent or de novo OAB symptoms after bladder neck slings.

Key Points: Voiding Dysfunction After Pubovaginal Sling

- Obstruction, DO, and impaired detrusor contractility are manifestations of voiding dysfunction from iatrogenic outlet obstruction after a PVS.
- The incidence of permanent urinary retention is usually less than or equal to 5%.
- Persistent urgency and UUI (8% to 25%) present more commonly as symptoms of bladder outlet obstruction after a PVS compared with frank urinary retention.
- A temporal relationship between the anti-incontinence surgery and the onset of voiding dysfunction is the key to diagnosis. Urodynamic studies may be helpful in these cases for diagnosis and to assist in making an appropriate treatment plan.
- Transient urinary retention usually resolves within 10 days, and obstruction from a PVS may improve or resolve with time. Therefore, most surgical interventions should be postponed until at least 3 months after surgery.
- Reported success rates of the surgical management of bladder outlet obstruction after a PVS procedure are 65% to 93%. The rate of recurrent SUI after urethrolysis is 0 to 19%.
- There are no preoperative variables that predict success or failure of urethrolysis. OAB symptoms are refractory in 50% of affected women after urethrolysis and contribute to a significant portion of reported failures.

Complications of Pubovaginal Slings

Pubovaginal Sling Perforation and Exposure

The incidence of PVS perforation and exposure is partially dependent on the composition of sling material. **Synthetic slings perforate 15 times more often into the urethra and are exposed 14 times more often in the vagina than autologous, allograft, and xenograft slings** (Blaivas and Sandhu, 2004). These numbers are based on a meta-analysis of 287 peer-reviewed articles (Leach et al., 1997). In this study, the urethral perforation rate was 0.02%, and the vaginal exposure rate was 0.007% in 1515 women who received synthetic slings. This is in contrast with a 0.003% urethral perforation incidence and 0.0001% vaginal exposure incidence in 1715 women who underwent autologous and allograft sling procedures. In subsequent studies, most perforations and exposures were associated with synthetic slings, particularly woven polyester slings (Amundsen et al., 2003; Bent et al., 1993; Chin and Stanton, 1995; Clemens et al., 2000; Duckett and Constantine, 2000; Kobashi et al., 1999; Myers and LaSala, 1998; Summit et al., 1992; Weinberger and Ostergard, 1995). Several cases of autologous and allograft sling perforations and exposures have been published (Amundsen et al., 2003; Blaivas and Sandhu, 2004; Bradley et al., 2003; Golomb et al., 2001; Handa and Stone, 1999).

Most urethral perforations are diagnosed 1 to 18 months after the original surgery, with a mean presentation time of approximately 9 months (Blaivas and Sandhu, 2004). Presenting symptoms often include urinary retention, urgency, and MUI. In addition, synthetic sling perforations and exposures may also be associated with vaginal discharge, vaginal pain, suprapubic pain, and recurrent UTIs. The etiology of these symptoms is usually multifactorial and may be related to the woman's tissue quality, surgical technique, or the sling material. Local tissue quality may be suboptimal from postsurgical scarring, urethral atrophy, estrogen deficiency, and radiation-induced ischemia. Errors in surgical technique include excessive sling tension, dissection too close to the urethra, or perforation of the urethra or bladder.

Urinary tract perforation by an autologous PVS is rare, with only four cases documented in the peer-reviewed literature. Golomb et al. (2001) and Handa and Stone (1999) each reported an individual case of an autologous PVS eroding through the mid-urethra. Possible contributing factors include misplacement or incorrect technique in sling passage or positioning, excessive tension, or traumatic urethral instrumentation after placement of a PVS (e.g., for clot evacuation or surveillance cystoscopy). In both aforementioned cases, the perforated portion of the sling was excised and the urethra was repaired. Clemens et al. (2000) described two cases of bladder dome perforation by an autologous rectus fascial PVS. The women had recurrent UTIs, dysuria, and UUI. One woman had a bladder calculus on the sling material visible on cystoscopy. The other had edema and visible suture at the dome. Both cases were likely caused by a missed bladder perforation after Stamey needle passage, underscoring the need for vigilant cystoscopy with 30- and 70-degree lenses during PVS surgery. Both cases were successfully managed with endoscopic removal of stitches and treatment of the stone. No further treatments were necessary.

Management of autologous and allograft sling urethral perforation usually involves incision or excision of the intraluminal sling portion and simple closure of the urethra (Blaivas and Sandhu, 2004). Rarely, additional coverage with measures such as a Martius flap may be required. **Because urinary tract perforation and vaginal exposure of synthetic PVS are more common and associated with significant morbidity, synthetic material is no longer used for bladder neck slings.** In fact, the ProteGen sling (Boston Scientific) was withdrawn from the market in January 1999 possibly because of the high urinary tract perforation rates (Clemens et al., 2000). Some authors believe that synthetic PVS sling perforation into the urinary tract necessitates complete removal of the sling and all other foreign materials (sutures, bone anchors, screws) whenever present (Blaivas and Sandhu, 2004). However, we believe that, as long as the synthetic material is no longer under tension, excised far away from the bladder and urethra, and not associated with infection or pain, it is not necessary to remove all of the foreign material. The technique for this removal is discussed in the Mid-Urethral Slings section later in this chapter.

The incidence of recurrent SUI after synthetic PVS removal in cases of urethral perforation is 44% to 100%, and treatment often involves a secondary PVS (Amundsen et al., 2003; Clemens et al., 2000; Kobashi et al., 1999). Flisser and Blaivas (2003) reported an 87% continence rate when perforations were managed with concurrent placement of a new PVS. Blaivas and Sandhu (2004) also noted that secondary procedures such as periurethral bulking agents and PVSs are successful in a majority of patients. However, if the bladder neck is involved with the perforation, the authors noted a much lower overall continence rate, even with the use of concomitant autologous slings at the time of reconstruction.

Pubovaginal Sling Nonurologic Complications

While the most common complications of PVS surgery are related to the urinary tract, significant nonurologic complications also occur. The authors of the 2009 update of the AUA guideline for SUI surgery performed an extensive meta-analysis of the literature and confirmed that the most common nonurologic complications were pulmonary, cardiovascular, neurologic, and gastrointestinal (bowel injury) (Appell et al., 2009). When considering all anti-incontinence procedures (retropubic and transvaginal suspensions, anterior colporrhaphy, and PVS), the panel estimated a death rate of approximately 3 per 10,000 procedures.

Anger et al. (2007a) analyzed Medicare claims data for short-term complications after sling surgery (mostly MUS) among female beneficiaries 65 years of age and older. A total of 1356 sling procedures were performed from 1999 to 2001, and, in the 3 months after surgery, 12.5% of women developed surgical or urologic complications and 34% were diagnosed with UTIs. One year after surgery, the following nonurologic complications were reported: bowel injury or obstruction (6.6%), cardiac complications (9.1%), thromboembolic complications (2.6%), pulmonary complications (15.3%), and other (22.1%). On multivariate analysis, nonwhite race was a risk factor for developing urologic and nonurologic postoperative complications. In addition, women 65 to 69 years of age were significantly less likely to experience nonurologic complications or undergo treatment for outlet obstruction or recurrent incontinence than women older than 75 years of age. In a similar review of greater than 21,000 female Medicare beneficiaries undergoing sling surgery between 2001 and 2011, Chughtai et al. (2016) cited rare adverse events within a 90-day postoperative window. The only exception was urinary retention, which was recorded in 11.3% of the women.

More specific information about the type of complications can be gleaned from the literature. In the SISTEr trial, rates of serious adverse events for the autologous PVS and Burch colposuspension groups were 13% and 10%, respectively (Albo et al., 2007). In the sling group, both deep venous thrombosis (DVT) and serious bleeding had an incidence of 0.3%. Although the authors did not describe the specific type of complication, there was also a 3.4% incidence of serious wound complications. The most common wound complications after autologous PVS surgery are wound infection, seroma, and incisional hernia. In their experience with over 500 patients, Blaivas and Chaikin (2011) reported wound infections and incisional hernias, each, in 1%. In another retrospective study of 247 women, the rate of incisional hernias was a similar 0.8% (Morgan et al., 2000). Although rare, incisional hernias related to harvesting the rectus fascia are an unfortunate serious complication of autologous PVS that usually require surgical correction.

Key Points: Complications of Pubovaginal Slings

- The incidence of perforation is dependent on the sling material, with synthetic slings being 15 times more likely to perforate into the urethra and 14 times more likely to become exposed in the vagina than other materials. For this reason, synthetic PVS are no longer used for support at the bladder neck.
- Vaginal exposures after synthetic slings typically manifest with vaginal discharge, pain, suprapubic pain, and recurrent UTIs and may require subtotal or total sling removal.
- The incidence of recurrent SUI after synthetic PVS urethral perforation is 44% to 100%, and treatment often involves a second (autologous) PVS.
- Perforation or exposure after autologous PVS is rare.

Mid-Urethral Slings

Mechanics, Anatomy, and Materials of Mid-Urethral Slings

Mechanics of the Mid-Urethral Sling

The integral theory posits that the most important factors in preserving continence are adequate function of the pubourethral ligaments, the suburethral vaginal hammock, and the pubococcygeus muscle (Petros and Ulmsten, 1990). An injury to any of these three components from surgery, parturition, aging, or hormonal deprivation can lead to impaired mid-urethral function and, subsequently, SUI. Urethral hypermobility is a sign of damage to these normal supporting structures of the urethra and not a cause of SUI.

Preoperative ultrasonography and MRI have demonstrated that the proximal urethra in women with SUI is often open at rest and, regardless of urethral mobility, movement of the anterior and posterior walls of the urethra during stress maneuvers most likely contributes to a shearing affect that opens the urethra and results in incontinence (Dietz and Wilson, 2004; Huang and Yang, 2003; Kociszewski et al., 2008; Masata et al., 2006; Sanders et al., 1994). Based on these observations, **it appears that a MUS works by impeding the movement of the posterior urethral wall above the sling, directing its motion in an anteroinferior or anterior direction. In addition, inward movement of the posterior urethral wall after placement of an MUS results in narrowing of the urethral lumen (compression).** This securing of the posterior wall of the urethra (with or without compression during stress maneuvers) is one theory of how MUS procedures achieve stress continence. In addition to this proposed mechanism for urethral support, some authors have proposed that MUS work through a mechanism of dynamic urethral kinking during stress events as seen on ultrasonography (Lo et al. 2001).

Ideally, a retropubic or transobturator MUS is placed loosely at the mid-urethra, and its function does not require the sling to be tight. The sling is anchored to the endopelvic fascia for retropubic-directed slings and to the obturator internus and externus muscle and fascia for transobturator-directed slings. Over time, the synthetic mesh sling becomes fixed in either of these two locations and provides support along its entire course inferior to the pubic symphysis and ischiopubic rami, and not just at the midline area posterior to the urethra. This broad support may be the reason why, in studies by Laurikainen and Killholma (2006), Gamé et al. (2006), Clifton et al., (2014) and Klutke et al. (2001), 50%, 70%, 79%, and 93% of women, respectively, remained continent after MUS incision for obstruction.

Several authors have found that lack of urethral mobility before retropubic and transobturator MUS is a prognostic factor for lower SUI cure rates, and that decreased urethral mobility postoperatively is associated with persistent incontinence (Haliloglu et al., 2010; Minaglia et al., 2005, 2009). Conversely, the postoperative persistence of significant urethral mobility is not associated with a poorer outcome. It appears that **lack of urethral mobility is a sign of a fixed urethra and ISD. Overall, women without urethral hypermobility do not respond as well to MUS surgery. A loosely placed MUS combined with a mobile urethra may allow the sling to compress the urethra during times of Valsalva and other stress maneuvers while remaining nonobstructive when the urethra is at rest.**

Despite the fact that transobturator and retropubic MUS are placed without tension, there is controversy about whether tension or resistance is ultimately created at the bladder outlet. In one study of over 400 retropubic MUS procedures, urodynamic studies before and after surgery confirmed a postoperative increase in voiding time but no difference in flow rate, urethral closure pressure, or urethral functional length (Meschia et al., 2001). A study by Lo et al. (2001) also showed no statistical difference in average flow, Qmax, PVR, MUCP, and functional urethral length in 82 women before and after retropubic MUS.

In contrast, urodynamics performed in 112 women before and after retropubic MUS showed consistent decreases in Qmax, increased mean PdetQmax, increased mean urethral resistance, and elevated PVR (Gateau et al., 2003). The authors concluded that retropubic MUS leads to obstructive changes in the bladder outlet. Sander et al. (2002) evaluated the voiding phase before and 1 year after retropubic MUS and found both subjective and objective changes in the voiding phase. Seventy-eight percent of women experienced more difficult voiding and significant decreases in Qmax, corrected Qmax, and average flow. PVR was also significantly increased, although no greater than 25% of capacity.

Unlike after retropubic and transobturator MUS, restriction of urethral mobility after SIMS may be associated with more favorable outcomes. Martan et al. (2009) analyzed 85 women after a SIMS with perineal ultrasonography, cough test, and validated questionnaires. Postoperatively, 62% had a negative cough test. The sling was noted to restrict urethral mobility, and a higher degree of restriction was associated with a higher likelihood of cure; however, this restrictive effect was noted to weaken within the first 3 months after surgery. A study of 57 women who underwent SIMS also showed that outcomes were poorer in women who had persistent urethral hypermobility after surgery (Spelzini et al., 2013). It is possible that SIMS efficacy is related to restriction of urethral mobility and that this restriction is required to secure the posterior urethral wall, achieve adequate urethral kinking, or compress the urethral lumen.

Anatomy of the Retropubic Mid-Urethral Sling

For a retropubic MUS, the trocars must pass through the retropubic space, which is also known as the *space of Retzius* or *prevesical space.* This space is bounded anteriorly by rectus abdominis muscles and the bony pelvis (pubic symphysis and ischiopubic rami). The lateral borders of the space are the bony pelvis and the obturator internus muscle. The bladder and proximal portion of the urethra lie posterior to this space. The endopelvic fascia (paravaginal connective tissue or pubocervical fascia) forms the inferolateral boundary of the prevesical space and is attached medially to the levator ani muscles at the bladder neck and inferior portion of the pubic symphysis. The endopelvic fascia is attached laterally to the ATFP and the ischiopubic rami. The endopelvic fascia separates the prevesical space from the vesicovaginal space. The prevesical space mainly contains loose connective tissue and adipose tissue. Obese women may have more adipose tissue in this space, and this anatomic finding may contribute to the lower rate of trocar-related bladder injuries seen in this patient population (Stav et al., 2010b).

The left and right dorsal nerves of the clitoris (DNC) run along the inferior surface of the ischiopubic rami and cross under the pubic bone approximately 1.4 cm from the midline (Achtari et al., 2006). After placing a retropubic MUS in 10 cadavers, the authors found that the sling was an average of 1.1 cm from the DNC at its closest point. The fact that the superior incisions for a retropubic MUS are typically made at least 2 cm from the midline should help ensure that the DNC are not injured by a trocar or sling. At a distance of 3.2 cm (laterally), the obturator vessels are the closest major vascular structures to a retropubic MUS (Muir et al., 2003).

The vesicovaginal space is the initial plane of dissection for a retropubic MUS. This space is bounded by the posterior wall of the bladder and the anterior wall of the vagina (Corton, 2013). The space extends to the proximal and middle urethra. Below this location, the posterior wall of the urethra and the anterior vaginal wall are fairly fused. A relatively thick periurethral fascia covers the posterior urethra. The female urethra is approximately 4 cm in length, and, therefore, an incision 1.5 cm from the meatus will provide access to the mid-urethra.

Anatomy of the Transobturator Mid-Urethral Sling

Like the retropubic MUS, transobturator MUS surgery begins with dissection in the vesicovaginal space. This dissection is carried out lateral to the urethra until the inferior border of the ischiopubic rami and pubic symphysis can be easily palpated. A trocar must traverse the obturator internus muscle, obturator membrane, and obturator externus muscle as it goes through the obturator foramen. Lateral to the obturator foramen are the adductor muscles (gracilis and adductor brevis muscles) of the thigh (Corton, 2013). The obturator nerve and vessels are located in the obturator canal at the superior aspect of the obturator foramen.

Several authors have performed cadaveric dissections to better understand the anatomic relationships of the transobturator MUS. Delmas et al. (2003) used the outside-in approach in 10 cadavers to detail the relevant pelvic anatomy in relation to the sling insertion path. In these dissections, the sling consistently passed 4 cm anterior and caudal to the obturator canal, confirming the relative safety of the obturator neurovascular structures. The authors also demonstrated that the sling traverses a plane between the perineal and levator ani musculature above the pudendal neurovascular pedicle.

Bonnet et al. (2005) performed the inside-out transobturator technique as described by de Leval (2003) in 13 cadavers to determine the sling path and proximity to surrounding structures. The authors noted that the sling never penetrated the adductor longus muscle and was a safe distance from neurovascular structures. However, in approximately 70% of cases, the implanted material traversed the adductor magnus, adductor brevis, and gracilis muscles during its path into the pelvis. At the level of the obturator foramen, the sling traverses the obturator externus and internus muscles as well as the obturator membrane. The distance between an inserted sling and the obturator nerve and vessels at the level of the obturator foramen ranged from 2.2 cm to 3 cm. The authors stated that hyperflexion of the hip and the rotational trajectory of the helical passer help ensure this separation. Also, the anterior branches of the obturator artery and vein are protected from injury by the bony architecture of the inferior pubic rami. Medially, the transobturator MUS enters the anterior compartment of the ischiorectal fascia, in the area of the levator ani membrane and obturator internus muscle. A properly placed sling remains outside the pelvic space and does not penetrate the levator ani muscular group. Lastly, transobturator MUS remain above the perineal membrane at all times, and the DNC, which is found caudal to the perineal membrane, is protected from injury during trocar passage.

A study by Whiteside and Walters (2004) further evaluated the obturator anatomy in relationship to sling insertion in 6 cadavers. The authors found that the mesh, on average, passed 2.4 cm inferior and medial to the obturator canal and that anterior and posterior divisions of the obturator nerve were 3.4 cm and 2.8 cm, respectively, away from the path of the trocar. However, they also noted that the trocar passed, on average, within 1.1 cm of the most medial and anterior branches of the obturator vessels (located behind the inferior pubic rami, as described by Bonnet et al., 2005). These authors concluded that a risk for injury does exist, and appropriate caution should be exercised.

The anatomic variations between the inside-out and outside-in transobturator MUS approaches have been compared, especially with regard to their association with adverse outcomes. The mean distance from the vaginal incision to the obturator membrane was 4.0 cm and 6.75 cm from the vaginal incision to the obturator neurovascular bundle in cadaver dissections after an inside-out transobturator MUS (Raders et al., 2005). At the obturator membrane, the closest point of the passer is only a mean distance of 2 cm from the obturator neurovascular bundle. This is the reason the curved passer is directed away from these structures and advanced. Also, an anterior branch of the obturator artery coursed medially along the exterior edge of the obturator foramen in 60% of the cadavers. However, similar to Bonnet et al. (2005), Raders et al. (2005) felt that the exterior bony rim of the obturator foramen protected this artery during an inside-out pass. However, they also postulated that this vessel could be potentially injured during an outside-in approach.

Anatomy of the Single-Incision Mid-Urethral Slings

For a SIMS, the plane of dissection is only in the vesicovaginal space. Although the trocars are much shorter, they are passed into the retropubic space or through the obturator foramen. As with other MUS procedures, cadaveric dissection aids in the anatomic localization of the SIMS. Using 14 embalmed and 5 fresh-frozen female bodies, Hubka et al. (2009) placed SIMS trocars bilaterally and measured the distances from the obturator bundle (obturator nerve and vessels). They found that the mean distances of the sling from the obturator nerve and vessels were 3.05 cm and 3.07 cm, respectively. Perforation of the fascia of obturator internus muscle occurred in 4.4%, and the authors felt that vascular injury, albeit unlikely, could theoretically occur. The position of the SIMS was not found to change with repositioning of the legs.

Mid-Urethral Sling Materials

In their initial description of the MUS, Ulmsten and Petros (1995) used Mersilene, Gore-Tex, Teflon, and Lyodura (cadaveric dura mater). However, because of complications related to other synthetic materials in the general surgery hernia literature, Ulmsten et al. (1998) eventually settled on a polypropylene, multifilamentous woven mesh and termed the procedure *intravaginal slingplasty* (IVS; Tyco Healthcare, Mansfield, MA). **Currently, almost all of the MUS products are constructed from a soft, loosely woven, polypropylene monofilament mesh with a pore size exceeding 75 µm.** As previously discussed, this material allows for optimal migration of host inflammatory components (leukocytes and macrophages) into the mesh for purposes of infectious surveillance and host wound healing (imbibition and inosculation). It has also been found that this material is optimal for inciting fibrous tissue ingrowth. This type of mesh is known as a type I mesh (Amid classification) and has previously been described in the general surgical literature as being favorable from the standpoints of its mechanical properties such as stretch and elasticity (Dietz et al., 2001, 2003).

UraTape (Mentor-Porgés, Le Plessis-Robinson, France) was the first transobturator MUS, and Delorme et al. (2003) were first to report initial outcomes. UraTape is a polypropylene, microporous sling with a central silicone core, and was eventually replaced by ObTape (Mentor-Porgés) because of a high rate of vaginal exposure likely related to the silicone core. However, possibly because of its semi-microporous (<50 µm) nature, vaginal exposures have also been reported with ObTape (Siegel, 2005; Yamada et al., 2006). A second-generation transobturator MUS developed by Mentor-Porgés (Aris transobturator tape) has a larger, 200-µm pore size that allows improved tissue ingrowth with less encapsulation. A unique transobturator mesh is the BioArc, which has a biologic (porcine dermis, InteXen) graft material that is sutured on either end to the polypropylene mesh. The biologic material actually occupies a suburethral position (de Leval, 2003; Delorme et al., 2003). While many retropubic and transobturator MUS products have been removed from the market, the available products are made of monofilament, macroporous woven polypropylene.

Key Points: Mechanics, Anatomy, and Materials of Mid-Urethral Slings

- The integral theory states that the most important factors to preserve continence are adequate function of the pubourethral ligaments, the suburethral vaginal hammock, and the pubococcygeus muscle. An injury to any of these three components from surgery, parturition, aging, or hormonal deprivation can lead to impaired mid-urethral function and, subsequently, urinary incontinence.
- Urethral hypermobility is a symptom of damage to the normal supporting structures of the urethra and not a cause of SUI.
- Initial MUS products were constructed of materials with smaller pore sizes. Currently, the majority of MUS are made of loosely woven, macroporous, monofilament polypropylene.

Mid-Urethral Sling Operative Procedures

Mid-Urethral Sling Patient Counseling

Because MUS surgery involves the implantation of a synthetic prosthesis, surgeons should thoroughly counsel their patients about the permanent nature of these products, and, although infrequent, unique and sometimes serious complications related to their use may occur. As with the PVS, women should also be counseled about the risk for transient and permanent voiding dysfunction after surgery. This should include a discussion of postoperative difficulty emptying the bladder and de novo urinary storage symptoms.

Mid-Urethral Sling Anesthesia, Patient Positioning, and Preparation

MUS surgery can be performed using local (with or without sedation), spinal, or general anesthesia, but the decision is based on patient, surgeon, and anesthesia provider preference. In the original description of the MUS, local anesthesia was used so that the woman would be able to perform an intraoperative cough stress test as a method of adjusting sling tension. It was believed that this would minimize the incidence of obstruction. However, several studies have failed to show a difference in the efficacy or safety of MUS performed under local versus spinal anesthesia (Adamiak et al., 2002; Wang and Chen, 2001). In one of these studies, 67 women underwent MUS under local anesthesia and 36 under spinal anesthesia, and there was no difference in the success rate after MUS or in the incidence of complications between the groups (Adamiak et al., 2002). The inability to perform a cough test in the spinal anesthesia group did not result in an increased incidence of postoperative obstruction. Hence, tensioning the sling according to cough stress test may not improve outcomes. Antibiotic and DVT prophylaxis, vaginal preparation, and patient positioning are performed as for the PVS procedure. Additional thigh flexion (≥70 degrees) may be beneficial during this procedure.

Surgical Approach for Retropubic Mid-Urethral Slings

The standard MUS consists of two specially curved 5-mm diameter insertion trocars and a 40-cm long and 1.1 cm wide segment of polypropylene mesh, although the width and length of the mesh and trocar diameter may vary slightly by manufacturer. The sling is typically covered with a clear plastic sheath, which protects the mesh from contamination and allows easy passage through host tissues. For the bottom-up technique, a rigid catheter guide is typically placed in the urethra with an 18-Fr Foley catheter to help deflect the bladder away from the path of trocar insertion. An ergonomic handle is attached to the trocar to aid in its manipulation. Fig. 125.8 shows some of the various types of slings and trocars that have been historically available. It must be noted that some of thes products may no longer be available on the market.

FIG. 125.8 (A to K) Mid-urethral sling trocars and prosthetics.

For MUS insertion under local anesthesia, approximately 5 mL of local anesthetic is injected into the vaginal area and into the planned suprapubic insertion skin sites. An additional 20 mL of local anesthetic is injected into the area along the posterior aspect of the pubic bone to the level of the urogenital diaphragm to anesthetize the retropubic space. Additional vaginal infiltration includes 10 mL injected on either side of the urethra to the level of the urogenital diaphragm.

After appropriate anesthesia, two small suprapubic stab incisions are created just above the level of the symphysis pubis, approximately 2 cm lateral to the midline. A third incision is made in the vaginal mucosa in the midline approximately 1.5 cm long and 1.5 cm proximal to the external urethral meatus. After the vaginal incision is created, minimal dissection is performed using Metzenbaum scissors under the vaginal flaps on either side to elevate the vaginal epithelium from the underlying periurethral tissue to the level of the pubocervical (endopelvic) fascia, which is not perforated. For the bottom-top technique, the trocar is then placed in the dissection tunnel immediately beneath the vaginal epithelium on one side of the urethra with the trocar tip situated in close proximity to the lower rim of the pubic ramus. With controlled pressure, the trocar is elevated through the endopelvic fascia, into the space of Retzius, through the rectus muscles, and through the previously created suprapubic skin incision. During this maneuver, the trocar is kept in close contact with the inferior surface of the pubic bone to avoid perforation of the lower urinary tract and also to avoid intraperitoneal entry. Tactile contact with the bone and slow graded pressure during trocar advancement ensure direct apposition of metal to bone and avoidance of bladder injuries.

Simultaneous deflection of the lower urinary tract is accomplished during insertion using the catheter guide and catheter with pelvic viscera deflected away from the site of needle insertion. The same maneuver is performed contralaterally so that each trocar exits through the appropriate skin incision. The technique for top-down trocar passage is very similar; however, a catheter guide with Foley in the urethra is typically not used, and the tip of the trocar is guided onto the index finger of the opposite hand and out of the vaginal incision lateral to the urethra.

Cystoscopy is performed to exclude trocar penetration of the lower urinary tract. The use of a 70-degree lens is essential, as is complete distention of the bladder with irrigant to exclude subtle tangential injury. **If perforation is noted, the trocar is withdrawn and passed once more with an effort to avoid further perforation.** Once cystoscopy has demonstrated no evidence of bladder injury, the bladder is drained and the mesh is brought through the incisions and the sling is tensioned. Tension adjustment is commonly performed by inserting a surgical instrument (clamp) or metallic sound between the sling and urethra while the protective plastic sheath is removed from the field. **In general, a MUS should be placed loosely at the mid-urethra because its function is not primarily related to compression.** Redundant mesh is then excised at the level of the suprapubic skin incisions, and the vaginal incision is closed with delayed absorbable suture. The skin incisions may be left open or closed per surgeon preference. (Fig. 125.9).

FIG. 125.9 Mid-urethral sling as placed via the retropubic approach.

Surgeons' views on sling tensioning vary considerably. A total of 596 surgeons (63% gynecologists, 37% urologists) from 56 different countries completed an Internet survey, with greater than 30% of respondents performing greater than 50 slings annually (Borazjani et al., 2017). Use of objective intraoperative tension evaluation methods was 15.6%, 7.8%, and 1.9% for intraoperative stress tests, cystoscopic evaluation of urethral coaptation, or Q-tip tests, respectively. Sixty-three percent indicated that they tension retropubic and transobturator MUS similarly, whereas 26.2% placed transobturator MUS under more tension, and 10.4% placed more tension on retropubic MUS. Those with fellowship training were 66% more likely to utilize leak point pressure results to inform the degree of tensioning (OR 1.66, CI 1.04 to 2.66).

Surgical Approach for Transobturator Outside-in Slings

The woman is placed in the dorsal lithotomy position with legs in hyperflexion (120 degrees). A small 1.5-cm midline vaginal incision is created 1.5 cm from the meatus as with the retropubic MUS, and dissection is carried out laterally to the ischiopubic ramus. A puncture incision is made in the crease between the labia majora and the thigh, at the notch along the internal edge of the inferior pubic ramus and the adductor longus tendon. With the woman in hyperflexion, the adductor longus tendon can be pinched with the thumb and index finger and the skin incision typically corresponds to location of the thumb. The obturator membrane is perforated, at which point resistance is noted by the operative surgeon. Using the nondominant index finger and identifying the landmarks of ramus and the obturator internus muscle, the trocar is turned in a medial orientation and advanced on the tip of the index finger and brought out through the vaginal incision. Inspection is carried out at this point to exclude inadvertent penetration of the vaginal fornix or associated urinary structures. The procedure is then repeated on the contralateral side. Cystoscopy to rule out urethral and bladder injury is recommended after trocar passage, and **it is important not to neglect a careful examination of the urethra.** The synthetic material is then attached to the trocar and brought out through the inner thigh stab wound. Tension is set on the sling by passing a clamp between the sling and urethra such that a surgical clamp can be passed easily between these two structures. Excess material is then cut at the skin puncture site, and the incisions are closed according to the surgeon's preference.

Surgical Approach for Transobturator Inside-Out Slings

The vaginal component of the procedure is the same as in the outside-in technique. Stab incisions are created approximately 2 cm superior to the horizontal line level with the urethra and 2 cm lateral to the labial folds, which will be the exit point for the helical passer. Once the device is inserted through the urethra and the upper part of the ischiopubic ramus is reached with the device, the obturator membrane is perforated sharply with scissors. The introducer is then passed at a 45-degree angle relative to the midline sagittal plane until it reaches and perforates the obturator membrane. The open side of the introducer is passed out facing the surgeon. The more distal end of the tubing is then mounted on the spiral segment of the helical passer and slipped along the open gutter of the introducer. The passer is aligned parallel to the sagittal axis and rotated so that the tip of the tubing exits the interthigh stab incision. The tubing is then removed from the passer until the first few centimeters of the mesh become externalized, and the procedure is repeated on the contralateral side. Next, cystoscopy is performed to ensure no injury to the bladder or urethra. All plastic covering sheaths are then removed simultaneously from the sling while maintaining no tension on the sling itself, using the technique previously described. Operative technique varies with insertion method (Fig. 125.10).

FIG. 125.10 Mid-urethral sling as placed via the transobturator approach.

Surgical Approach for Single-Incision Slings

Each of the SIMS has a proprietary method of placement that varies by manufacturer. In general, the sling devices consist of a short segment of loosely woven polypropylene mesh with two harder, pointed ends that allow it to anchor in place. A curved stainless steel trocar or other type of applicator device is used to push the ends of the sling into a secure position. The sling is placed under the mid-urethra and can be fixed in the hammock position (Fig. 125.11A) into the obturator internus muscle or in the U-shaped position (see Fig. 125.11B) into the connective tissue of the urogenital diaphragm (endopelvic fascia) behind the pubic bone (Meschia et al., 2009).

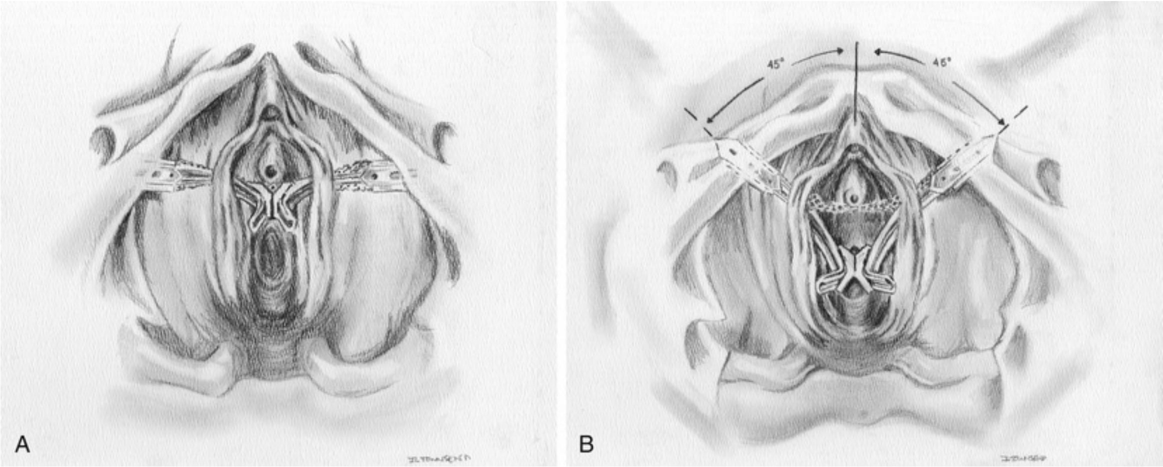

FIG. 125.11 Mid-urethral sling as placed via a single-incision approach. (A) Hammock style. (B) U position.

The procedure is performed with the patient in the dorsal lithotomy position (with sequential compression devices in place) with a significant degree of thigh flexion (≥70 degrees). A Foley catheter is placed before the procedure to ensure that the bladder is fully decompressed before passage of the device. As previously described, the patient receives parenteral sedation, and approximately 5 mL of 0.9% normal saline is used to hydrodistend the anterior vagina. After the vaginal incision is created, minimal dissection is performed using Metzenbaum scissors under the vaginal flaps on either side to elevate the vaginal epithelium from the underlying periurethral tissue to the level of the pubocervical fascia, which is not perforated. One trocar of the device is placed in the right dissection tunnel immediately beneath the vaginal epithelium and advanced up to the ischiopubic bone and into the obturator internus muscle, where the trocar holder anchors the sling edges. The left side is introduced in the same way, creating a hammock-shaped sling. Definitive sling tension is achieved when the tip of a hemostat is easily passed between the urethra and the sling. Cystoscopy with a 30-degree rigid cystoscope should be performed before completion of the procedure. This step is essential to avoid the future morbidity of repeat surgery for intravesical or urethral mesh. Urinary efflux from both ureteric orifices is confirmed. **Our experience suggests that the tension of the SIMS should be tighter than the classic retropubic or transobturator MUS surgeries to**

achieve the same result.

Outcomes of Mid-Urethral Slings for Predominantly Stress Urinary Incontinence

In reviewing the extensive outcomes for the MUS, several caveats must be mentioned. Outcomes are reported in varying fashions using different tools, durations of follow-up, and overall definitions of success and failure. Furthermore, studies may include women who have undergone previous anti-incontinence procedures or those who are undergoing concomitant POP repair. These factors should be kept in mind when attempting to compare different groups and procedural nuances.

Outcomes for Retropubic Mid-Urethral Slings in Patients With Predominantly Stress Urinary Incontinence

The initial study of the retropubic MUS reported an 80% author-defined success rate (Ulmsten et al., 1996). A subsequent prospective multicenter trial that included 130 women with SUI revealed success, improvement, and failure rates of 91%, 7%, and 2%, respectively, at 1 year (Ulmsten et al., 1998). In this first multicenter study, complication rates were low, but did include one bladder mesh perforation and one wound infection possibly associated with mesh exposure. The rate of voiding dysfunction was also relatively low, with only one woman experiencing retention for 12 days, which resolved spontaneously, and three women with less than 3 days of voiding dysfunction that required short-term CIC.

Nilsson and Kuuva (2001) evaluated 161 consecutive retropubic MUS operations (28% of whom had failed prior anti-incontinence surgery, 11% had ISD, and 37% had MUI). At a mean follow-up of 16 months, the overall objective cure rate was 87%, with 7% of women significantly improved, and another 5% considered failures. The trocar bladder puncture rate at the time of insertion was 3.7%, and 4.3% of women experienced short-term de novo voiding dysfunction. Urgency symptoms arising after surgery occurred in 3% of women, yet 80% of those who had preoperative urgency symptoms had relief of those symptoms at their 16-month visit. No serious complications were noted.

Since then, the MUS (and most notably the TVT) has become the most studied surgical procedure in the incontinence literature. Several single-center studies have reported outcomes at follow-up periods exceeding 10 years (Table 125.6). Success rates range from 48% to 97% depending on the definition, but typically approach 85%. There does appear to be a tendency for higher failure rates in older women and those with ISD in the long-term. The rate of complications continues to be low, and the Austrian Urogynecology Working Group reported no serious complications and no mortality from data compiled within the Austrian central registry, beginning in 1998 (Tamussino et al., 2001). It is interesting to note that 363 (45%) of the women in the registry had an MUS in combination with other procedures such as POP repair.

The efficacy of the retropubic MUS has been amply compared with other anti-incontinence procedures. Among the retropubic MUS versus Burch colposuspension comparisons, the trials by Ward and Hilton enrolled the greatest number of patients and reported data at short-, medium-, and long-term follow-up periods (Ward and Hilton, 2002, 2004, 2008). After 6 months, the 175 women randomized to retropubic MUS and 169 to Burch had no significant difference in cure rates. The MUS was associated with more operative complications (i.e., bladder trocar injury), and the colposuspension was associated with more postoperative complications and longer recovery. At 2 years of follow-up, the overall cure rates noted were relatively low, with 63% of the MUS patients and 51% of colposuspension patients being cured. Also, there were significantly more women in the colposuspension group needing CIC ($P < 0.0045$) and surgery for pelvic organ prolapse ($P < 0.0042$) than in the MUS group. At long-term follow-up (5 years), there was no difference in cure rates and, consistent with earlier studies, POP was seen more commonly in the Burch group. Unlike earlier reports of high (27%) rates of de novo urgency and urgency incontinence in the literature after colposuspension (Jarvis, 1994), Ward and Hilton (2008) reported that less than 2% of women experienced this problem after MUS and less than 5% of women after colposuspension. In another comparison between retropubic MUS and Burch colposuspension, El-Barky et al. (2005) found operative time, duration of hospital stay, and time until return to normal activity significantly shorter in the MUS groups.

A MUS has also been compared in RCTs to other MUS procedures, with a recent systematic review including 81 trials with 12,113 women (Ford et al., 2017). The transobturator and retropubic approaches were compared in 55 trials with 8652 women. With follow-up periods of up to 1 year, the rate of subjective cure of both approaches are similar (RR 0.98, 95% CI 0.96 to 1.00; 36 trials, 5514 women), ranging from 62% to 98% in the transobturator group and from 71% to 97% in the retropubic group. Short-term objective cure was likewise similar (RR 0.98, 95% CI 0.96 to 1.00; 40 trials, 6145 women). Fewer trials reported medium-term (1 to 5 years) and longer term (over 5 years) data, but subjective cure was similar between the groups (RR 0.97, 95% CI 0.87 to 1.09; 5 trials, 683 women; and RR 0.95, 95% CI 0.80 to 1.12; 4 trials, 714 women). In the long term, subjective cure rates ranged from 43% to 92% in the transobturator group and from 51% to 88% in the retropubic group. The retropubic MUS appears to be more effective than the transobturator MUS in women with ISD (Rechberger et al., 2009). Likewise, Schierlitz et al. (2008) observed that, at 6-month follow-up, 13% of the women who underwent transobturator MUS for ISD required further surgery, compared with 0% of those who underwent retropubic MUS.

Retropubic MUS were associated with higher morbidity, but the overall rate of adverse events remained low. The rate of bladder perforation was lower, as expected, after transobturator MUS (0.6% vs. 4.5%; RR 0.13, 95% CI 0.08 to 0.20; 40 trials, 6372 women), as were major vascular/visceral injuries, mean operating time, operative blood loss, and length of hospital stay. Postoperative voiding dysfunction was also less frequent after transobturator MUS (RR 0.53, 95% CI 0.43 to 0.65; 37 trials, 6200 women). Rates of groin pain were higher in the transobturator group (6.4% vs. 1.3%; RR 4.12, 95% CI 2.71 to 6.27; 18 trials, 3221 women), but suprapubic pain was lower in the transobturator group (0.8% vs. 2.9%; RR 0.29, 95% CI 0.11 to 0.78). The overall rate of vaginal tape erosion/exposure/extrusion was low in both groups: 24/1000 instances with transobturator compared with 21/1000 for retropubic MUS (RR 1.13, 95% CI 0.78 to 1.65; 31 trials, 4743 women). There was limited evidence to suggest that repeat incontinence surgery in the long term was more likely after transobturator MUS (RR 8.79, 95% CI 3.36 to 23.00; 4 trials, 695 women). A retropubic bottom-top route was more effective than the top-down approach in terms of subjective cure (RR 1.10, 95% CI 1.01 to 1.19; 3 trials, 477 women), and it was associated with significantly lower rates of voiding dysfunction, bladder perforations, and vaginal tape exposures (Andonian et al., 2005; Lord et al., 2006; Tseng et al., 2005).

Several additional randomized comparisons have been performed between the down-to-up retropubic MUS (TVT) and other slings. Arunkalaivanan and Barrington (2003) compared the TVT with the Pelvicol PVS in a questionnaire-based study and found no difference in subjective cure rates at both 12-month and 36-month follow-up. TVT was compared in three studies with IVS, a multifilament, microporous polypropylene mesh material passed in a top-to-down manner. Rechberger et al. (2003) reported no differences in cure rates at 13 months of follow-up with 50 women in each group. Complications were similar, except for acute postoperative urinary retention occurring significantly more commonly in the TVT group. Meschia et al. (2006) compared the TVT and IVS with intermediate follow-up and reported subjective cure rates of 80% for TVT and 78% for IVS, and objective cure rates of 85% for TVT and 72% for IVS. Eight (9%) of the women who underwent IVS experienced vaginal erosion, compared with none in the TVT group. Lim et al. (2005) compared the TVT with the IVS and SPARC (a monofilament, macroporous polypropylene MUS passed in a top-to-down approach) in the SUSPEND trial. There was no significant difference between the cure rates between TVT (87.9%), IVS (81.5%), and SPARC (71.4%). There was a significantly greater rate of mesh exposure in the SPARC group. Balakrishnan et al. (2007) followed a subgroup of IVS patients from the Lim group (2005) for up to 30 months and found 13% with sling erosions, requiring removal. Of the 29 women (47%) from this initial IVS group seen 12 to 34 months postoperatively, 24% experienced sling erosion with associated sinus formation, requiring sling removal.

Outcomes for Transobturator Mid-Urethral Slings in Patients With Predominantly Stress Urinary Incontinence

Since its initial description by Delorme (2001), the transobturator approach MUS has become a viable method for effectively treating female SUI. Long-term continence rates have overall been high (Table 125.7). Because of its relatively recent introduction, 10-year outcome data have only recently become available, and reported continence rates range from 43% to 92% based on a variety of subjective (questionnaires and QoL single-item assessment) and objective (cough stress test, physical examination) measures**. Overall, the**

outcomes of transobturator MUS procedures in patients with predominantly SUI are similar to those of the retropubic MUS.

In 2010, Richter et al., published results of a large prospective, randomized trial comparing the retropubic MUS (*n* = 298) with the transobturator MUS (*n* = 299) with 12 months of follow-up. The objective cure rates as determined by a negative stress test, pad test, and no retreatment for the retropubic and transobturator groups were 80.8% and 77.7%, respectively (no statistically significant difference). The rate of voiding dysfunction requiring surgery was significantly higher in the retropubic group (2.7% vs. 0%). Of the 597 women in the original trial, 404 (68%) were enrolled in a 5-year observational cohort (Kenton et al., 2015). At the 5-year mark, the success was approximately 8% greater in women who underwent the retropubic MUS (51.3% vs. 43.4%, 95% CI –1.4, 17.2), not meeting prespecified criteria for equivalence. Satisfaction decreased during the 5 years but remained high and similar between arms (79% for the retropubic MUS and 85% for the transobturator MUS, *P* = 0.15). Additional RCTs have confirmed similar short- and medium-term success rates between the two approaches, as discussed in the previous section (Ford et al., 2017). The AUA SUI guideline cited Grade A evidence and made a Moderate recommendation that, in index patients who select MUS surgery, physicians may offer either the retropubic or transobturator MUS (Kobashi et al., 2017).

Short- and medium-term subjective cure rates between transobturator MUS passed using an in-to-out technique compared with an out-to-in approach were similar (RR 1.00, 95% CI 0.96 to 1.06; 6 trials, 759 women; and RR 1.06, 95% CI 0.91 to 1.23; 2 trials, 235 women) (Ford et al., 2017). Voiding dysfunction was more frequent in the inside-out group (RR 1.74, 95% CI 1.06 to 2.88; 8 trials, 1121 women), but vaginal perforation was less frequent in the inside-out approach (RR 0.25, 95% CI 0.12 to 0.53; 3 trials, 541 women). The SUI guidelines panel also state that, when performing transobturator MUS in women with stress-predominant urinary incontinence, surgeons may perform either the in-to-out or out-to-in technique (Kobashi et al., 2017).

Outcomes for Single-Incision Mid-Urethral Slings in Patients With Predominantly Stress Urinary Incontinence

Surgical treatment of SUI has expanded to include SIMS. This technology was first approved by the FDA in 2006 (TVT-Secur [TVT-S], Gynecare, Ethicon). Neuman (2008) performed a prospective observational study of 100 consecutive women with a hammock-style SIMS and compared postoperative outcomes between the first 50 women and the last 50. At 12 months, the objective failure rate went down from 20% to 8% between the two groups, with the sling being placed closer to the urethra. Four women in the first group had vaginal perforation with the inserter, and this complication was avoided in the second group by widening the submucosal tunnel. The mesh exposure rate decreased from 12% to 8% by the creation of deeper submucosal tunnels. There was one case of a paravesical self-remitting hematoma. Otherwise, the authors reported no cases of bladder or urethral perforation, urinary tract infection (UTI), wound infection, or intraoperative bleeding. At 12-month follow-up, the objective cure rates in the two groups were 88.6% and 93.5%.

In 2009, Dmochowski et al. reported preliminary results from one of the largest trials of the SIMS, with 29 sites participating in 8 countries. Effectiveness was measured by a standing cough stress test and an Incontinence Quality-of-Life (I-QoL) instrument. In this study of 642 women, 64.5% had a SIMS in a hammock (fixed into the obturator internus muscle) position, and 35.5% had it in the U position (fixed into the endopelvic fascia toward the retropubic space). Also, 65.3% had SUI and 34.7% had stress-predominant MUI. Intraoperative complications included one bladder perforation (0.2%) and three cases of bleeding greater than 200 mL (0.5%). Postoperatively, there was 1 reported case of retention (0.2%), 10 UTIs (1.6%), 6 cases of voiding dysfunction (0.9%), and 15 cases of de novo urgency (2.3%). There were five cases of mesh erosion (0.8%). Improvements in QoL at 3 months were sustained at 12 months. Objective continence via the cough test was 89% at 6 months and 87.5% at 12 months.

As befitting a relatively new approach, there is currently a dearth of long-term outcome data. However, there are a number of randomized trails comparing the "SIMS" to the transobturator MUS. Zhang et al. (2015) performed a systematic review of five RCTs encompassing 678 women who underwent SIMS (*n* = 361; Ajust™, CR Bard Inc., Covington, GA, USA) and TVT-O/TOT (*n* = 317) (Dati et al., 2012; Grigoriadis et al., 2013; Masata et al., 2013; Mostafa et al., 2013; Schweitzer et al., 2012). Three of these studies were available only in abstract form, and one compared 2 SIMS procedures, Ajust and TVT-Abbrevo (Dati et al., 2012). The authors' meta-analysis did not reveal a significant difference in patient-reported or objective cure rates between the two procedures (RR = 0.95, 95% CI 0.87 to 1.04, $P > 0.05$; and, RR = 0.97, 95% CI 0.90 to 1.05, $P > 0.05$, respectively). There were no significant differences between the two procedures in terms of postoperative pain, lower urinary tract injuries, postoperative voiding dysfunction, de novo or worsening of preoperative urgency, vaginal exposure, and need for repeat anti-incontinence surgery. The SIMS group had significantly less groin pain.

Since that publication, several additional studies have addressed the comparison between SIMS and transobturator MUS. Schellart et al. (2018) randomized 97 women to MiniArc and 96 to Monarc, with 77% and 78% of the original cohorts meeting 3-year follow-up, respectively. The subjective cure rates were not significantly different between the SIMS and transobturator MUS, 86% vs. 87% (risk difference –0.6%, 95% CI –12% to 11%), respectively. The objective cure rates were also not significantly different, 89% vs. 89% (risk difference 1.3%, 95% CI –9% to 11%), respectively. Complication rates were low in both groups. Likewise, Masata et al. (2016) randomized women to undergo TVT-O and Ajust, and at 1 year, 47 women in the TVT-O group and 49 in the Ajust group were available for evaluation. No differences in subjective cure rates or objective cure rates were observed. In the Ajust and TVT-O groups, the rates for subjective cure were 89.8 % and 91.5 %, respectively ($P = 1.0$, OR 1.22, 95% CI 0.24 to 6.58), and the rates for a negative stress test were 89.8 % and 87.2 %, respectively ($P = 0.76$, OR 0.77, 95% CI 0.17 to 3.32). In the Ajust group, two women reported de novo pain during sexual intercourse. Chang et al. (2015) performed a retrospective analysis of 136 women, 76 of whom underwent transobturator MUS (Align) and 60 who underwent a SIMS (Ajust). Women treated with SIMS had statistically significantly shorter operation time ($P = 0.003$), less intent to treat ($P < 0.05$), and earlier postoperative discharge ($P =$

0.001), and estimated operative blood loss, postoperative pain, and complications were similar between the two groups. Subjective and objective cure rates were not significantly different between the two groups (93% vs. 88% success rate in each group). Bianchi-Ferraro et al. (2014) randomized 56 women to TVT-O and 66 to TVT-S. At 2-year follow-up, objective cure rates for TVT-S and TVT-O groups were 77.3% and 83.6%, respectively, and subjective cure rates were 75.7% and 80.3% respectively, with no statistically significant differences between the groups. There was a significant improvement in all KHQ domains in both groups ($P < 0.001$). The most common perioperative complication was thigh pain associated with TVT-O, and vaginal exposure was observed in 5.3% and 7.5% of TVT-O and TVT-S cases, respectively.

A recent Cochrane systematic review by Nambiar et al. (2017) identified 31 RCTs or quasi-RCTs involving 3290 women that compared outcomes after SIMS compared with other anti-incontinence procedures. The following SIMS were included in this review: TVT-S; MiniArc (American Medical Systems, Minnetonka, MN); Ajust; Needleless (Mayumana Healthcare, Lisse, The Netherlands); Ophira (Promedon, Cordoba, Argentina); Tissue Fixation System (TFS PTY Ltd., Sydney, Australia), and CureMesh (DMed Co. Inc., Seoul, Korea). No studies compared SIMS versus no treatment, conservative treatment, colposuspension, laparoscopic procedures, or traditional PVS.

Women were more likely to have persistent or recurrent incontinence after SIMS than after retropubic MUS (121/292, 41% vs. 72/281, 26%; RR 2.08, 95% CI 1.04 to 4.14). SIMS was associated with higher risk for de novo urgency (RR 2.39, 95% CI 1.25 to 4.56). SIMS resulted in higher incontinence rates compared with inside-out transobturator MUS (30% vs. 11%; RR 2.55, 95% CI 1.93 to 3.36). The adverse event profile was also significantly worse with higher risks for vaginal exposure (RR 3.75, 95% CI 1.42 to 9.86) and bladder and/or urethral erosion (RR 17.79, 95% CI 1.06 to 298.88). Postoperative pain was less common with SIMS (RR 0.29, 95% CI 0.20 to 0.43), and rates of long-term pain or discomfort were marginally lower, but the clinical significance of these differences is questionable. Subanalysis revealed that the higher risk for incontinence was principally associated with use of the TVT-S, and this device has since been withdrawn from the market. The evidence was insufficient to reveal a difference in incontinence rates with other SIMS compared with inside-out or outside-in transobturator MUS. Risks of postoperative and long-term groin/thigh pain were slightly lower with SIMS, but overall evidence was insufficient to suggest a significant difference in the adverse event profile for

SIMS compared with transobturator MUS. Evidence was also insufficient to permit a meaningful sensitivity analysis of the other SIMS compared with transobturator MUS. The only significant differences were observed in rates of postoperative and long-term pain, and in duration of the operation, which marginally favored SIMS. Overall, results show that TVT-S is considerably inferior to retropubic and inside-out transobturator MUS, but additional evidence is required to allow any reasonable comparison of other SIMS and transobturator MUS. When two SIMS procedures were compared, there was insufficient evidence to suggest a significant difference between any of the available products.

Likewise, Song et al. (2018) analyzed 45 RCTs with 7295 participants that compared different MUS procedures. TVT, TOT, and Ajust had a higher objective cure rate than TVT-O (OR = 0.76, 95% CI 0.61 to 0.94) and TVT-S (OR = 0.41, 95% CI 0.28 to 0.60). TVT, TOT, and TVT-O had a superior subjective cure rate than TVT-S (OR = 0.29, 95% CI 0.15 to 0.56) and Ajust (OR = 0.45, 95% CI 0.20 to 0.91). With TVT as the reference, TVT-S had a statistically lower postoperative complication rate (OR = 0.39, 95% CI 0.16 to 0.89) and TVT-O, TVT-S, and TOT had significantly lower bladder perforation rates. There were no obvious differences between the five treatments for tape erosion. The AUA SUI guidelines panel cited Grade B evidence and made a Conditional recommendation that physicians may offer the SIMS to index patients undergoing MUS surgery with the patient informed as to the immaturity of evidence regarding their efficacy and safety (Kobashi et al., 2017).

There is some evidence in the literature that SIMS may have decreasing efficacy with longer follow-up. In a study of 96 women prospectively followed after TVT-S, the subjective cure rate decreased significantly between years 1 and 3 (85.4% to 72.9%) (Han et al., 2012). In another study by Masata et al. (2012) with 2 years of follow-up, 197 women were randomized to receive SIMS or transobturator MUS. The authors found that the SIMS had significantly lower objective (69% vs. 93%) and subjective (75% vs. 90%) cure rates.

Outcomes of Mid-Urethral Slings for Mixed Urinary Incontinence

Evidence suggests that MUS are successful for women with MUI symptoms as well. However, interpretation of these studies should be done with caution because many outcomes are reported on the basis of symptoms only with no urodynamic substantiation. In a retrospective analysis of 112 consecutive women with SUI and MUI by Jeffry et al. (2002), the objective cure rate measured by clinical and urodynamic examination was 89.3% at a mean follow-up of 25 months. Objective cure was defined as no evidence of stress incontinence, a negative stress test result, and no urinary retention or PVR volume greater than 150 mL. No difference was found in the objective cure rate between women with SUI and those with MUI. The overall subjective cure rate via the Contilife questionnaire was 66% and was lower than the objective cure in both women with SUI (69.3%) and those with MUI (54.2%). The type of incontinence did not alter the incidence of postoperative voiding difficulty. Ten of the 24 women with MUI had persistent urgency symptoms.

Holmgren et al. (2005) evaluated the outcome of the retropubic MUS in women with SUI and MUI with mailed questionnaires 2 to 8 years postoperatively. This was a large cohort of 970 women, and the 78% response rate was remarkable. Ultimately, 580 women with SUI and 112 women with MUI were eligible for analysis. Categorization of incontinence was based only on a positive stress test and a history of leakage immediately preceded by urgency, and urodynamic studies were not performed. Women with MUI were significantly older than the women with SUI (mean age 67 years vs. 61.2 years), and adjustment for age was made in the analysis. In addition, women with MUI had a statistically significant higher body mass index (BMI), rate of cesarean delivery, history of radiation, and prevalence of urinary frequency than those with SUI. The SUI cohort had a durable 85% subjective cure rate after 3 and 8 years of follow-up; however, only 60% of the 112 women with MUI were cured 3 years after surgery, and outcomes declined steadily thereafter. By 6 to 8 years postoperatively, the cure rate in women with MUI was only 30%. In addition, urgency and episodes of urgency incontinence increased with time after the MUS. The study design inherently limits the interpretation of results, as the lower cure rate in the MUI cohort may be a function of the confounding variables such as age, radiation, and higher BMI.

In a similar Finnish study, 191 women who had undergone MUS were evaluated by examination or telephone interview at a mean follow-up of 17 months (Laurikainen and Killholma, 2003). Sixty-four (34%) had preoperative subjective MUI, and postoperative cure was based on self-reporting of complete dryness in any stress situation. None underwent preoperative urodynamic evaluation. At latest follow-up, 88% of the 191 women were completely cured, with the cure rate in women with MUI being significantly lower than in those with SUI (69% vs. 97%). Undergoing concomitant surgery did not impact cure rates compared with women having MUS alone, and 60% of the women with MUI considered their urgency and UUI improved, as well. The authors suggested that, on the basis of these results, preoperative urodynamic studies should be performed in women with MUI before anti-incontinence surgery.

Segal et al. (2004) evaluated 98 women after MUS explicitly to answer the question of what happens to UUI postoperatively. The outcomes included subjective symptoms, rate of anticholinergic use before and after MUS, and QoL questionnaires, and women who had concomitant surgery were excluded from analysis. Sixty-five women were identified as having UUI, and follow-up occurred at 3 months and 1 year. On the basis of preoperative subjective symptoms, the urgency component resolved in 63% after MUS. Two women with complaints of subjective UUI only and urodynamic SUI had persistent UUI requiring anticholinergic drug treatment. Seventy-five women had preoperative urinary frequency and urgency, which resolved in 57% after MUS. Thirty (58%) of the 52 women using anticholinergics preoperatively no longer needed medication after surgery. Only 4 women (4.1%) began anticholinergics for the first time after MUS. Women with prior anti-incontinence surgery were eight times more likely to have postoperative OAB requiring use of an anticholinergic. MUS surgery resulted in statistically significant improvement in QoL scores postoperatively in women with stress-predominant MUI and SUI with urinary frequency and urgency.

Rezapour and Ulmsten (2001) retrospectively reported the efficacy and safety of MUS in 80 women with MUI without preoperative urodynamic evidence of DO. At 5-year follow-up, 85% were cured, and an additional 4% were improved on the basis of pad testing and symptom questionnaire. The researchers concluded that urodynamic studies were essential before surgery to analyze presenting symptoms. Only one woman had prolonged urinary retention (6 weeks), and 8% were found to have small hematomas with one woman undergoing exploration for bleeding.

In 2008, Paick et al. reported short-term outcomes of retropubic and transobturator MUS surgeries in women with MUI and found no significant difference in cure rates for the SUI component. Preoperative DO was an independent risk factor for treatment failure of the UUI component. Athanasiou et al. (2009) compared the efficacy of retropubic and transobturator MUS for treatment of urinary incontinence in women with MUI and idiopathic DO. There were no subjective differences in outcome, yet women undergoing retropubic

MUS were less likely to have persistent DO postoperatively. Kulseng-Hanssen et al. (2008) evaluated outcomes of retropubic MUS in 1113 women with MUI based on the woman's most bothersome concern (i.e., SUI, UUI, or equal stress and urgency components) and observed no difference in cure rates among the three groups. Women with predominantly SUI had significantly better results at 7 and 38 months than the other two groups, especially the patients reporting mainly UUI. Eleven percent of women had an increase in UUI at 38-month follow-up. The authors concluded that patients with predominant urgency incontinence have poorer results than those with predominantly stress incontinence.

In women with urodynamic SUI and subjective OAB undergoing retropubic MUS, Leron et al. (2009) noted an 89% cure rate and 9% improvement in SUI, with 62% improvement in OAB symptoms. There was no change in the severity of symptoms in one-third of the women and de novo OAB symptoms developed in 6%.

Ballert et al. (2008) found no difference in storage, voiding, or total score on the AUA Symptom Index between women with SUI and those with MUI, or those undergoing retropubic versus transobturator MUS. Sinha et al. (2008) used the Medical, Epidemiologic, and Social Aspects of Ageing (MESA) questionnaire and other outcome measures for short-term evaluation of the retropubic MUS in women with MUI. SUI and UUI were either cured or improved in 78% and 75% of women, respectively. The postoperative global impression of outcome noted great or moderate improvement in 75% of patients and reduction in mean MESA scores of 69% ($P < 0.001$). Duckett et al. (2008) used perineal ultrasonography in 77 women with DO and urodynamic SUI to determine whether the position of a retropubic MUS has any effect on the resolution of irritative symptoms. They found that resolution of urinary storage symptoms is not dependent on placement of the sling under a specific portion of the urethra.

Three studies have attempted to correlate preoperative variables with outcomes of retropubic MUS procedures in women with MUI (Duckett and Basu, 2007; Gamble et al., 2008; Panayi et al., 2009). Duckett and Basu (2007) compared pressure-flow studies before and after the MUS and observed that a significantly decreased Qmax after MUS was associated with persistent OAB symptoms. Women with DO resolution postoperatively had significantly higher flow rates compared with those with persistent DO, supporting a possible partial obstruction in women with persistent DO. Gamble et al. (2008) found that age, nocturia, maximum capacity, and choice of sling procedure affected the persistence of DO and UUI. The lowest rate of DO was seen after transobturator MUS, followed by retropubic MUS and then PVS. Panayi et al. (2009) found higher median preoperative opening detrusor pressure in women with DO after MUS surgery (33 vs. 26 cm H_2O, $P < 0.05$).

Four groups have focused on treatment of MUI with a transobturator MUS (Abdel-Fattah et al., 2014; Botros et al., 2007; Paick et al., 2008; Tahseen and Reid, 2009). Botros et al. (2007) compared the de novo urgency and resolution of DO and UUI among women undergoing the Monarc (125), TVT (99), and SPARC (52) procedures. De novo urgency was significantly lower in the Monarc group (8% vs. 33% for TVT and 17% for SPARC, $P = 0.04$); however, rates of de novo DO and resolution of preoperative DO and UUI did not differ among the three groups. Paick et al. (2008) performed 72 TVT, 22 SPARC, and 50 transobturator MUS in women with MUI. The authors found no significant differences in SUI cure rates or overall incontinence cure rates among the three groups. The presence of preoperative DO was associated with high UUI persistence in all three groups. Tahseen and Reid (2009) performed a transobturator MUS in 58 women and found 77% and 19% SUI and improvement rates, respectively. Additionally, UUI was persistent, improved, and cured in 21%, 36%, and 43% of women with MUI, respectively.

Overall, although most studies have reported that women with SUI have a higher cure rate than those with MUI, MUS procedures appear to be an effective treatment for those women with concomitant urgency and UUI. In addition, several studies have demonstrated improvement in OAB symptoms and less need for anticholinergic medications in women with MUI after MUS surgery. It must be noted that women with urge-predominant MUI are more likely to require combination therapy addressing both stress and urge symptoms. Finally, de novo urgency and UUI may develop after any sling procedure.

Outcomes of Mid-Urethral Slings for Intrinsic Sphincteric Deficiency

ISD has been an important risk factor for failure of conventional anti-incontinence procedures. It is difficult to evaluate the efficacy of surgical treatment for ISD because no universally accepted definition presently exists. However, as previously stated in the Pubovaginal Sling section, ISD is often defined urodynamically as an ALPP less than 60 cm H_2O or an MUCP less than 20 cm H_2O. **What is clear from the current literature is that the success of MUS is lower in women with a fixed urethra (no urethral mobility) and low leak point pressures. In addition, a preoperatively fixed urethra seems to be more predictive of a poorer outcome (no cure) than a low leak point pressure.** Thus, women with fixed urethrae have poor outcomes after MUS surgery regardless of leak point pressure.

In 2001, Rezapour et al. (2001) published a prospective 4-year follow-up of 49 women with ISD who underwent retropubic MUS. Forty-one of these women had urethral hypermobility, and the remainder had immobile urethrae. In the entire cohort, 74% of women were cured, and 12% were improved. None of the women with fixed urethrae were cured, and only three improved. Other studies support lower cure rates of retropubic MUS in women with low leak point pressures when rates of urethral hypermobility (fixed vs. nonfixed urethras) are not statistically different (Paick et al., 2004). Urethral mobility before MUS procedures has been shown to be predictive of success, and the greater the mobility in the proximal urethra with Valsalva, the higher the incontinence cure rate (Fritel et al., 2002). Leak point pressures alone have not been shown to predict outcome after an MUS procedure (Gutierrez Banos et al., 2004; Rodriguez et al., 2004). Therefore, **low leak point pressures are not necessarily a contraindication to retropubic MUS surgery.** Leak point pressures in the era of the MUS should be correlated with the woman's physical examination and used to counsel patients about their risk for a reduced chance of success.

Several additional studies have been performed to assess the clinical effectiveness of the retropubic MUS procedure in women with ISD (Bai et al., 2007; Ghezzi et al., 2006; O'Connor et al., 2006; Rechberger et al., 2009). In all of these studies, women had urodynamic SUI with Valsalva leak point pressure (VLPP) less than 60 cm H_2O. Ghezzi et al. (2006) noted a 94% cure rate in 35 women seen at 12.5-month follow-up. Two of the three women in whom the procedure failed were noted to have a fixed urethra preoperatively. Bai et al. (2007) compared 1-year treatment outcomes of the retropubic MUS in women with ISD (31) and non-ISD (80). Whereas there was a significant difference in cure rates between the ISD (87%) and non-ISD groups (100%) at the 1-month follow-up, there was no significant difference by 1 year after surgery. Rechberger et al. (2009) conducted a prospective, randomized trial with a follow-up of 18 months comparing the clinical effectiveness of retropubic and transobturator MUS, and, although the efficacy of both techniques was comparable, the retropubic route was more efficacious in the ISD group.

Although Delorme (2001) and Mellier et al. (2004) noted ISD in 15.6% and 28% of their transobturator MUS cohorts, respectively, outcomes were similar to their non-ISD populations. O'Connor et al. (2006) were the first group to examine the early outcomes of the transobturator approach in women stratified by high (>60 cm H_2O) and low (<60 cm H_2O) VLPP categories. The odds of continued SUI after transobturator MUS surgery were 12 times greater for women with low VLPP compared with those with high VLPP. In general, no preoperative predictors of outcomes using either clinical or urodynamic parameters have been established to determine overall results of MUS procedures. Even though the Richter et al. (2010) study comparing retropubic and transobturator MUS was not designed to look at ISD, all of the women underwent preoperative urodynamic studies. The authors found that VLPP and MUCP had no effect on the outcomes of the sling surgeries; however, the degree of urethral mobility was not recorded.

The evidence from RCTs regarding MUS outcomes specifically for ISD is sparse. A recent systematic review encompassed 55 RCTs comparing retropubic and transobturator MUS, 12 of which included women with ISD (Ford and Ogah, 2016). Only 8 of these trials of 399 women reported data specifically for this cohort (Deffieux et al., 2010; Karateke et al., 2009; Kim et al., 2005; Oliveira et al., 2008; Porena et al., 2007; Rechberger et al., 2009; Schierlitz et al., 2008; Tanuri et al., 2010). Six of the trials used VLPP less than or equal to 60 H_2O, 1 trial used either VLPP less than or equal to 60 H_2O or MUCP less than or equal to 20 H_2O, and 1 trial used MUCP less than or equal to 30 H_2O for their definitions of ISD. At short- and medium-term follow-up, 150 of 199 (75.4%) and 171 of 200 (85.5%) in the transobturator and retropubic MUS groups, respectively, were subjectively cured. This represents a 12% relative risk reduction in achieving cure with the transobturator route. Objective cure was reported by five trials of 324 women and reported no statistically significant difference between the two groups, with 69.2% of 159 women achieving cure after transobturator MUS and 76.4% of 165 after the retropubic MUS. Postoperative voiding dysfunction and de novo urgency and UUI were not statistically different between the two groups. The authors found that the need to undergo repeat incontinence surgery in the long-term was higher in the cohort undergoing transobturator MUS (147 women; RR 14.4, 95% CI 1.95 to 106).

More recently, Wlazlak et al. (2017) cited an 81.6% success rate after TVT in

109 women with ISD at 6 months of follow-up. Patients with a relative tape position toward one-half of urethral length had a higher cure rate ($P = 0.0003$), and cure rates decreased significantly with decreasing urethral mobility. Kim et al. (2016) likewise found that TVT (95.2%) was more effective than TOT (82.7%; $P = 0.009$) in 157 women with ISD.

Overall, **clinical experience with the MUS suggests that it is beneficial in the management of SUI in women with ISD, as long as there is preoperative urethral mobility.** In addition, the absolute reported rates of cure and improvement for women with ISD are within the range of reported results experienced with other types of procedures.

Outcomes of Mid-Urethral Slings for Recurrent Stress Urinary Incontinence

There are limited data specifically addressing the efficacy of MUS procedures as secondary surgery in women with recurrent incontinence. Several small studies with relatively short follow-up addressed the issue (Azam et al., 2001; Kuuva and Nilsson, 2002, 2003; Lo et al., 2002; Rardin et al., 2002a;; Rezapour and Ulmsten, 2001). As with the majority of SUI literature, comparison of these studies is hampered by differences in the definitions of cure, improvement, and failure and outcome criteria. Also, the population of patients in most studies of recurrent SUI may be biased by the inclusion of women in whom bulking agents had failed. Despite these limitations, cure rates of MUS surgery after prior failed anti-incontinence surgery range from 81% to 90%. Upon further review of these articles, several trends emerge. The procedure can be performed in the same way as it is performed for primary SUI. The complication rates are similar to that of retropubic MUS done for primary SUI, but the risk for bladder perforation appears to be higher in women who have had one or more prior retropubic suspensions. Also, as is the case with primary surgery, the failure rate is higher in women with immobile urethrae.

Rezapour and Ulmsten (2001) have one of the longest follow-up periods (4 years) for a cohort of women undergoing retropubic MUS for recurrent SUI. The 34 women had undergone 64 different anti-incontinence surgeries, and exclusion criteria included presence of significant prolapse, DO, or ISD (MUCP <20 cm H_2O). Twenty-four women had a hypermobile urethra, and 10 had a less-mobile urethra. Twenty-eight (82%) were cured by objective and subjective parameters, and 9% were improved. Only one bladder perforation occurred in a woman with a prior Marshall-Marchetti-Krantz (MMK), and no significant complications were encountered. Postoperative voiding dysfunction was negligible with no change in PVR urine after 8 weeks. These results were durable for up to 5 years.

Only a few series present the outcomes of women treated with a repeat MUS for recurrent SUI (Biggs et al., 2009; Lee et al., 2007a; Riachi et al., 2002; Tsivian et al., 2007; Villet et al., 2002). In these studies, the cure rates for women with recurrent SUI are higher for retropubic than for transobturator MUS. Tsivian et al. (2007) found that, in 12 women undergoing repeat MUS, the only procedure that failed was a repeat transobturator MUS. In another study, the cure rate for the repeat transobturator approach was 63% compared with 92% after repeat retropubic MUS (Lee et al., 2007a). A possible explanation for this difference is the angle of the sling, as the retropubic MUS has a U shape, which may provide more lateral support and, hence, more dynamic obstruction during increases in intra-abdominal pressure. In addition, the outside-in approach to the transobturator MUS may require wider dissection of the periurethral area, leading to potential sling migration. Salvage procedures are performed in some women in whom the initial MUS failed because of underlying ISD or who now have a fixed urethra from the initial surgery. This is consistent with the evidence of high success with retropubic slings for patients with a component of ISD.

In 2010, Stav et al. reported the outcomes in 1035 women after primary MUS surgery and 75 women after repeat MUS surgery (Stav et al., 2010a). Repeat MUS surgery was significantly less effective at curing incontinence than a primary sling (62% vs. 86%, $P < 0.001$). The rates of complications were similar between the two groups; however, the repeat group had a significantly higher rate of de novo urgency and UUI. All of the women underwent preoperative urodynamic studies, and the rate of preoperative MUI was similar between the two groups. It is interesting to note that the rate of preoperative ISD was significantly higher in the repeat MUS group (31% vs. 13%, $P < 0.001$). In 2013, Agur et al. performed a meta-analysis of the 10 RCTs of MUS that addressed recurrent SUI. The review included 350 women with a mean follow-up of 18.1 months. The authors found no significant difference in subjective cure rates in these women between retropubic and transobturator MUS surgery.

Key Points: Mid-Urethral Slings for Recurrent Stress Urinary Incontinence

- A repeat mid-urethral synthetic sling procedure for persistent or recurrent SUI is a viable option for select patients in whom the initial procedure has failed.
- Some studies show cure rates to be higher for retropubic slings than for transobturator slings. This may be the result of unequal rates of ISD in different study populations.

Outcomes of Mid-Urethral Slings in Patients With Pelvic Organ Prolapse

A large proportion of women with SUI have associated POP, and several studies have explored the outcomes of concomitant MUS and POP surgery. The advantage of using a synthetic MUS over an autologous PVS or retropubic suspensions at the time of POP repair is that operative time is reduced and blood loss from the MUS portion is less. **However, a theoretical risk for MUS with concomitant transvaginal surgery is that the increased dissection will increase exposure of the graft, leading to greater rates of infection, perforation, or vaginal exposure. Additionally, increased blood loss or anatomic distortion from the concomitant POP procedures could increase the rate of sling migration, postoperative voiding dysfunction, or obstruction. Finally, appropriate MUS tensioning in women with occult SUI (only seen with POP reduction) may be challenging.**

Although most studies tend to be small and have short-term follow-up, **results suggest that the MUS can be added to POP surgery with minimal morbidity and high success rates** (73% to 93%) (Jomaa, 2001; Huang et al., 2003; Meltomaa et al., 2004; Wei et al., 2012). Even in questionnaire-based assessments 3 years after surgery, the data do not show a statistical difference in the cure rate of SUI and incidence of urgency symptoms after MUS surgery alone or in combination with other vaginal surgery (Meltomaa et al., 2004). While transient urinary retention occurred more often in women undergoing combined surgery, rates of urethrolysis were low and not statistically different between groups. The reporting of urinary retention rates is limited by variations in the definition of retention, and, thus, caution must be exercised when interpreting outcomes.

Gordon et al. (2001) performed a “prophylactic” retropubic MUS during POP repair in 30 women with occult SUI. None of the women had undergone prior anti-incontinence surgery, and all had urethral hypermobility. At a mean follow-up of 14 months, no woman developed symptomatic SUI, but three had a positive stress test during postoperative urodynamic assessment. Six of nine women had persistent urgency, and four developed de novo urgency without evidence of obstruction. No woman had urinary retention lasting more than 2 weeks.

Five-year data from a prospective analysis of a large group of women undergoing MUS surgery for occult SUI combined with transvaginal repair of second- or third-degree POP revealed a low incidence of complications (Groutz et al., 2004). One bladder perforation was managed conservatively without consequence, and two women experienced extended voiding difficulty requiring catheterization for greater than 7 days. However, urethrolysis was not necessary in either case. Three cases of vaginal erosion were documented. Two women developed recurrent symptomatic SUI, and another 15 were found to have asymptomatic, urodynamically confirmed SUI. Eight women developed de novo UUI, and 72% of the 18 women with preoperative UUI had persistent UUI postoperatively.

The Cochrane Group found 16 randomized or quasi-randomized controlled trials that included significant data on bladder outcomes after a variety of POP surgeries (Maher et al., 2013). The authors concluded that women undergoing POP repair may benefit from having concomitant anti-incontinence, especially if they had overt SUI or if they were continent and had occult SUI demonstrated preoperatively. Following POP repair, 12% of women developed de novo urgency and UUI, and 9% developed de novo voiding dysfunction. Previous Cochrane reviews concluded that the addition of a retropubic MUS to transvaginal or abdominal POP surgery may reduce the incidence of postoperative SUI, but issues of cost and associated adverse effects were unclear (Maher et al., 2008). More recently, van der Ploeg et al. (2016) randomized 47 women with occult SUI to POP surgery alone and 43 to POP surgery with MUS. At 12 months, a greater number of women in the MUS group reported absence of SUI (86% vs. 48%; RR 1.79, 95% CI 1.29 to 2.48). No women in the MUS group received additional treatment for postoperative SUI, and 13% of women in the control group had a secondary MUS.

Although concurrent surgery does not appear to alter continence rates after MUS, its impact on efficient voiding or postoperative retention remains in question. Sokol et al. (2005) noted no significant difference in median days to voiding and incidence of urinary retention based on prolapse repair status in 267 women (66% having concurrent POP repair). However, increasing age, decreasing BMI, and postoperative UTI were independent predictors of longer time to adequate voiding. A history of incontinence surgery was the only predictor of urinary retention, but there was a significant difference in the rate of urethrolysis between the group undergoing MUS alone and the group undergoing MUS with POP repair.

Unlike most reports, Partoll (2002) found that urinary retention is far more common after combined procedures than MUS alone. While the 11-month cure rate was 94%, the rate of urinary retention in those women with concurrent anterior or posterior repair was an alarming 43%. It must be noted that urinary retention was defined as not meeting the criteria for catheter removal on postoperative day 2. Rather than the more flexible expectations in other studies, it is the expectation of efficient voiding 48 hours of surgery that most likely accounts for the higher rate of retention in this study. Of the 1356 sling cases from a Medicare claims database, Anger et al. (2008) isolated 467 (34%) who underwent concomitant POP repairs. Women in this group were significantly more likely to be diagnosed with postoperative outlet obstruction (9.4% vs. 5.5%, $P < 0.007$), but less likely to undergo a reoperation for SUI or POP within 1 year of follow-up.

When MUS are placed for urodynamic or occult SUI at time of prolapse repair, the risk for intervention for obstruction is equivalent to the risk for intervention for SUI if no MUS was placed (8.5% and 8.3%, respectively) (Ballert et al., 2009). Likewise, the risk for intervention for SUI in women with clinical (i.e., subjective) SUI but no urodynamic or occult SUI and no MUS was 30%.

MUS placed with either transvaginal or laparoscopic-assisted vaginal hysterectomy and anterior or posterior colporrhaphy have been shown to have success rates similar to those in published series of MUS surgery alone (Huang et al., 2005). Complication rates are also in accordance with other MUS series, with 2% bladder trocar injury, 11% postoperative urgency, and 11% postoperative voiding difficulty. A study specifically looking at the complications and cure rates of MUS performed with or without vaginal hysterectomy found that there was no overall difference (Darai et al., 2002). There was a trend in the MUS-hysterectomy group toward more bladder perforations and lower postoperative urinary flow rates, but these relationships were not statistically significant. Objective and subjective cures for this group were 93% and 75%, respectively, which was not significantly different from the MUS-alone group.

Anger et al. (2007b) evaluated the relationship between provider specialty and outcomes of sling surgery, specifically related to concurrent prolapse management. Using 1999 to 2000 Medicare data, the researchers found that urologists performed 1063 sling procedures, and gynecologists performed 246. Urologists performed concomitant POP repairs in 29% of cases versus 56% among gynecologists ($P < 0.0001$). Postoperatively, urologists were more likely to perform a repeat anti-incontinence procedure (9% vs. 5%, $P = 0.024$) and POP repair (26% vs. 12%, $P < 0.0001$). These findings suggest that urologists should identify and manage prolapse at the time of evaluation of urinary incontinence to avoid the morbidity and cost of repeat surgery.

Wei et al. (2012) presented their results of the Outcomes Following Vaginal Prolapse Repair and Midurethral Sling (OPUS) trial. This trial attempted to determine whether the use of a concomitant “prophylactic” retropubic MUS prevents the development of SUI in women undergoing POP surgery who had no clinical (subjective) SUI preoperatively. Sham incisions were made in the control arm. A total of 327 women without clinical incontinence completed 1-year follow-up, and urinary incontinence (allowing for subsequent treatment of incontinence) was present in 27% and 43% of women in the sling and sham groups, respectively ($P = 0.002$). The number needed to treat with a sling to prevent one case of SUI at 12 months was 6.3. The rates of trocar bladder injury, UTI, and bleeding, although low, were all significantly higher in the MUS group. It is important to note that some of the women in the sham group (without subjective SUI) may have had occult SUI and, thus, contributed to the higher failure rate in this group.

The practice of placing a true “prophylactic” MUS (i.e., in a woman with no subjective, overt, occult, or urodynamic SUI) at the time of POP surgery is controversial. Proponents cite the minimally invasive nature and low complication rate of the MUS and the potential to minimize the chance of postoperative SUI, and opponents cite the possibility of creating postoperative obstruction and de novo storage symptoms in a woman with a preoperative absence of these symptoms. The literature regarding this topic is sparse. A systematic review by Matsuoka et al. (2015) identified seven studies addressing a prophylactic anti-incontinence procedure at the time of POP repair, three of which employed a TVT and one a TVT-O. Based on these limited findings, the authors concluded that prophylactic MUS reduced the risk for SUI after surgical correction of severe POP. Conversely, Dillon et al. (2012) reported complications such as mid-urethral strictures, infected MUS components, and secondary incontinence/POP requiring surgery in a group of 10 women who underwent revisions of “prophylactic” MUS. **Neither of the authors advocates the placement of a true “prophylactic” MUS**.

Outcomes of Mid-Urethral Slings in Elderly Women

Although there is a large body of literature that demonstrates the efficacy and low morbidity of MUS, there is a paucity of data evaluating the effect of advanced age on outcomes. Aging affects the lower urinary tract both anatomically and functionally. **The aging lower urinary tract may have a higher rate of DO, UUI, and ISD, and emptying abnormalities related to impaired contractility are also more common in elderly persons.** Older women are more likely to have had prior procedures for incontinence and therefore may have higher rates of urethral fixation. More severe vaginal atrophy related to long-standing lack of salubrious estrogen support in the older woman could pose a greater risk for poor or delayed healing and mesh exposure after MUS surgery. In addition, older patients may be at greater anesthetic risk as a result of medical comorbidities that could complicate the surgery, the surgical outcome, or the postoperative course.

A few small studies have evaluated the safety and efficacy of MUS in older women (>70 years of age). The most robust of the studies was a prospective comparison of 460 consecutive women who underwent MUS surgery with a mean follow-up of 26 months (Gordon et al., 2005). In this study 157 (34%) were elderly, and all women underwent urodynamic evaluations preoperatively and 3 months after surgery. Significantly higher rates of preoperative MUI were seen in the elderly cohort (31% vs. 23%). Intraoperative complications were infrequent in either group, although there were significantly fewer bladder trocar injuries in the elderly population. The incidence of postoperative fever, UTI, wound infection, and hematoma formation was similar in the two groups. Older women did experience more perioperative morbidities, such as pulmonary embolism (2), cardiac arrhythmia (2), DVT (1), and pneumonia (1), whereas there was only a single case of cardiac arrhythmia in a younger woman. Older women experienced no increased risk for vaginal exposure, and the rates of postoperative voiding dysfunction necessitating catheterization for greater than 1 week were low and similar between groups. Cure rates in the elderly and younger patients were 93% and 94%, respectively. Rates of UUI were similar between groups, but the rate of de novo UUI was significantly greater in the older patients (18% vs. 4%).

A smaller study of 76 women documented a similar rate of postoperative de novo UUI (18.4%) in elderly women undergoing MUS (Sevestre et al., 2003). One strength of this study is that the degree of urethral hypermobility was characterized. Of these women, 53% had urethral hypermobility (positive Q-tip deflection >30 degrees), 29% had undergone prior anti-incontinence procedures, and 4 (5.3%) had urodynamic DO. At a mean follow-up of 24.6 months, 67% of the women were cured as determined by questionnaire and examination, and 10 (13%) failed, and all of these women had negative Q-tip tests preoperatively. Satisfaction with the procedure was 82%, and rates of dissatisfaction were higher in those with de novo UUI. For the older women with a negative Q-tip test, the cure rate was 71%, compared with 100% in those with a positive Q-tip test. The rate of immediate urinary retention was 26%, but only 1 woman had urinary retention for more than 1 week.

Liapis et al. (2006) also correlated the degree of urethral hypermobility and outcomes of MUS surgery in women 65 to 85 years of age. The overall cure rate of 76% correlated positively with greater bladder neck mobility. In women in whom the Q-tip displacement was less than 30 degrees, 42% became continent, whereas 90% of those with a greater than 30-degree deflection were continent. Eighty percent of those women with an angle less than 10 degrees remained incontinent. Cure rates were similar in women older than 70 years of age and younger women after Burch colposuspension and MUS (Pugsley et al., 2005). There was an increased incidence of UTI in the elderly Burch colposuspension and MUS patients, and older women also required more long-term CIC after Burch colposuspension.

The cure rates in older women with urethral hypermobility appear to be comparable to those in younger women. Complication rates vary, with some studies citing a higher rate of age-related morbidities but no apparent increase in intraoperative complications. Jha et al. (2009) found that age did not significantly affect outcomes for SUI reduction or improvement in QoL after retropubic MUS. **Postoperative voiding dysfunction and increased de novo urgency do appear to be more common in older women and may affect older women more significantly.** Postoperative urgency symptoms have been reported in as many as 60% of older women, and 44% develop the symptom de novo (Allahdin et al., 2004). Bafghi et al. (2005) noted higher cure rates (98% vs. 79%; $P = 0.001$) and higher satisfaction rates (93% vs. 67%) in younger women. This difference was attributed to higher rates of de novo and persistent UUI in the older age group.

Another important measure of MUS success in elderly women is assessment of QoL. At a mean of 22 months after retropubic MUS, 67 women were evaluated with a validated health-related QoL instrument, the King's Health Questionnaire (Walsh et al., 2004). Statistically significant improvement was demonstrated in SUI, frequency, urgency, and UUI in both age groups. SUI was improved by 91% and 80% in the younger and older groups ($P = 0.037$ and $P = 0.046$, respectively). There was also significant improvement in both age groups in incontinence impact, role limitations, physical limitations, social limitations, emotions, and severity measures. Although MUS surgery was overall successful in the elderly, the hospital stay was 6 days, suggesting that the postoperative morbidity in this age group was significant. Campeau et al. (2007) compared elderly women who either underwent a retropubic MUS or had to wait 6 months for surgery. The women who underwent surgery had a significantly higher QoL ($P < 0.0001$), but, not surprisingly, only the group that underwent MUS experienced bladder perforation (23%) and urinary retention (13%).

Hellberg et al. (2007) mailed a questionnaire to 970 women who underwent MUS with a mean follow-up of 5.7 years. Older women were significantly more often on hormone replacement therapy, had lower education, and had a history of recurrent UTIs, previous vaginal repair, and previous anti-incontinence surgery. Likewise, older women more commonly had MUI and required longer hospitalization postoperatively. The unfavorable cure rate among the older women (56% vs. 80%, $P = 0.0001$) was a result of a higher failure rate for SUI rather than for urgency symptoms.

A multicenter, prospective randomized clinical trial was performed to compare MUS surgery versus delaying surgery for 6 months (control group) in 69 older women with SUI (Campeau et al., 2007). The main outcome measures included the I-QoL, the Patient Satisfaction Questionnaire, and the Urinary Problems Self-Assessment Questionnaire. At 6 months after randomization, the group who underwent immediate MUS surgery had significant improvement in QoL and patient satisfaction and had fewer urinary concerns compared with the group of women waiting for the same surgery. It is important to note that no age-related morbidity was observed in the immediate surgery group.

The rate of persistent SUI after retropubic or transobturator MUS appears to be higher in the elderly population, potentially caused by preoperative factors such as concomitant UUI or less urethral mobility. The elderly population also has a higher incidence of de novo urgency and UUI after MUS surgery. Additionally, although there may be some initial increase in perioperative morbidity, MUS surgery does appear to be safe in the elderly. Lastly, although the literature is insufficient to support one anti-incontinence procedure over another for the elderly woman, it can be concluded that **elderly women should not be excluded from potentially curative MUS surgery based on their age alone.**

Outcomes of Mid-Urethral Slings in Obese Patients

Obesity has an intimate relationship with SUI, and the prevailing connection is attributed to increased intra-abdominal pressure (Cummings and Rodning, 2000; Subak et al., 2009). Additionally, neurologic and metabolic mechanisms have been proposed, likely supporting a multifactorial pathophysiology (Callaghan et al., 2016; Heliövaara, 1987). As such, obese women may frequently develop SUI and may benefit from corrective anti-incontinence surgery.

Two reviews evaluated the existing literature regarding MUS procedures in the obese (Fuselier et al., 2018; Osborn et al., 2013). In total, the authors identified 30 studies that evaluated retropubic, transobturator, and single-incision MUS in the obese population. Several conclusions can be drawn from the data. First, both retropubic and transobturator MUS procedures are associated with success rates exceeding 80% in obese women and vary somewhat depending on the definition of cure. Second, success rates in obese women appear to be lower when compared with non-obese women, with several long-term observational studies suggesting that obesity is a risk factor for TVT failure (Aigmueller et al., 2011; Serati et al., 2012, 2017b). Likewise, a 5-year secondary analysis of an RCT evaluating retropubic and transobturator MUS revealed that obese women continued to experience lower cure rates than nonobese women (Brennand et al., 2017). Of the women in the nonobese group, 87.4% of 95 women were objectively cured according to the 1-hour pad test, in comparison to 65.9 % out of 44 obese women ($P = 0.003$). Subjective cure also differed between the two cohorts, with 76.7% out of 116 nonobese women being cured compared with 53.6% of 56 of the obese women ($P = 0.002$). Third, the few studies evaluating SIMS in the obese reveal conflicting outcomes. While Meschia et al. (2013) found poorer outcomes in the obese population after SIMS, Tommaselli et al. (2016) did not. It must be noted that nearly one-half of the 206 women in the former study underwent the TVT-S (which has been associated with higher failure rates), and the latter study used the BMI cutoff of 25 kg/m^2, thus grouping overweight women with the obese. Finally, outcomes in morbidly obese women (BMI >35 kg/m^2) appear to be lower than those in the overweight and obese population (McKenna et al., 2016; Yonguc et al., 2015).

While it was originally thought that obese women may be prone to more surgical complications after undergoing MUS, the data largely refute this. In a systematic review of pooled data from 13 studies, Weltz et al. (2015) did not detect a significant difference in rates of urinary retention or sling excision between obese and nonobese women. Chen et al. (2007) also found no statistical difference in the proportion of women who had at least one perioperative complication (20% [obese] vs. 15% [non-obese]) after undergoing vaginal surgery. As may be expected, obese women were more likely to have an operative site infection (adjusted OR: 5.5; 95% CI 1.7 to 24.7; $P = 0.01$]. Bladder punctures during RP MUS appear to be less common in the obese (Dunivan et al., 2009; Revicky et al., 2011; Weltz et al., 2015). On the other hand, Zyczynski et al. (2015) found that a BMI greater than or equal to 30 reduced the likelihood of OAB symptom improvement after SUI surgery (OR 0.57; 95% CI 0.36 to 0.88). Additionally, Cadish et al. (2017) found that, after adjusting for age and activity level, overweight and obese women had significantly increased risk for postoperative-onset pain vs. normal BMI women undergoing in-to-out TO MUS.

Key Points: Mid-Urethral Sling Surgery Outcomes in Patients With Concomitant Prolapse Repair and in Elderly and Obese Women

- The literature supports the use of MUS in a variety of special populations of women. Efficacy and safety of MUS are not compromised in the elderly, the obese, or those undergoing concomitant vaginal surgery.
- A few small studies suggest that concomitant vaginal surgery places a patient at higher risk for delayed return to normal voiding and urinary retention. However, limitations in study design prevent a strict comparison of the data.
- Current sling data is difficult to interpret because of the lack of standard

definitions of cure and improvement and lack of standard outcome measures.

- Absolute conclusions about the use of MUS in special populations should not be made until larger prospective multicenter studies have been performed.

Complications of Retropubic, Transobturator, and Single-Incision Mid-Urethral Slings

Over the past 10 years, there has been a 27% increase in the rate of surgery for SUI, and a large portion of that increase is directly caused by the growing popularity of the MUS (Jonsson Funk et al., 2012). However, in 2010 the FDA released a revised statement alerting the public to safety concerns regarding the use of synthetic mesh for POP and SUI surgery (FDA, 2010). The FDA became aware of problems related to synthetic mesh because of information contained in the Manufacturer and User Facility Device Experience (MAUDE) database. According to MAUDE data, from 2008 to 2010 there were 1371 voluntary and involuntary self-reported medical device reports of complications related to MUS, and a significant portion of those were mesh perforation and exposure (FDA, 2011).

While the **overall incidence of complications with all MUS procedures is low,** it is important to note that postoperative QoL may be affected just as much by the incidence of postoperative voiding difficulties, UTIs, and other adverse consequences of the surgery itself as it is by SUI cure or improvement. The Finnish MUS registry demonstrated a pronounced learning curve for surgeons adopting the new MUS technology (Kuuva and Nilsson, 2003). This registry is unique in that all of the nation's MUS procedures are recorded in a single data bank, and, therefore, the results are reflective of the entire national experience with this novel procedure. Another registry in Austria includes greater than 5000 cases but does not involve all of the surgeons in the country (Tamussino et al., 2001). **The rates of bladder trocar injury in the two aforementioned national registries were 2.7% and 3.8%, respectively, and the rates of voiding dysfunction and wound healing problems were 7.6% and 1%, respectively.** A more comprehensive look at complications in randomized prospective trials and large retrospective studies is presented in eTable 125.8.

[d] Retrospective survey of pelvic surgeons in Australia and New Zealand.

[e] Nine patients.

[f] Postoperative suprapubic ultrasonography performed on all patients.

NR, No record or authors did not comment on this complication; *RPS,* retropubic sling; *SS,* single-incision sling; *TOS,* transobturator sling.

Modified from Osborn DJ, Kaufman MR, Dmochowski RR. Complications after surgery for stress urinary incontinence. *Urologické Listy* 4:39–44, 2013.

As previously mentioned, the term *perforation* means that the polypropylene mesh has either entered the urinary tract (urethra, bladder, or ureters) or has penetrated bowel. The term *exposure* refers to the occurrence of visible or palpable mesh in the vagina or skin that is not covered by overlying tissue. For the purpose of this discussion, *trocar injury* refers to the passage of the trocar into the urethra or bladder at the time of sling placement.

The exact cause of these complications is debatable, but it most likely arises from a combination of patient and technical factors. These factors include patient body habitus, subclinical infection, poor tissue ingrowth into the sling, disturbed wound healing, rolling or twisting of the sling, excessive friction between host tissue and the sling, sling material properties, iatrogenic injury, and surgeon technical error (Domingo et al., 2005; Kobashi and Govier, 2003; Stav et al., 2010b)**. Biomechanical properties of the sling material have also been shown to play a major role in the incidence of complications related to mesh exposure.** Although various materials have been historically used for sling implants, there has been a trend in the contemporary literature toward the use of macroporous, polypropylene slings. The increased pore size of these materials allows for excellent tissue ingrowth, promotes integration with the surrounding host tissues, and decreases encapsulation and infection (Dietz et al., 2001, 2003; Slack et al., 2005). Adherence to meticulous surgical technique and use of polypropylene mesh with favorable biomechanical properties should help the surgeon minimize complications.

Mid-Urethral Sling Mesh Exposure

Vaginal mesh exposure is a rare complication after the MUS (Fig. 125.12). In a review of prospective trials and large retrospective studies, **the rate of vaginal mesh exposure was 0.5% to 8.1%** (see eTable 125.8). Most cases of vaginal mesh exposure manifest within a few weeks to a few months after the MUS procedure. **Symptoms** of vaginal exposure include vaginal discharge (with variable constituents and different amounts of blood and inflammatory components), a palpable rough surface in the vagina, sexual discomfort (including partner related), pelvic pain, inguinal discomfort, and lower urinary tract symptoms (urgency, frequency, persistent incontinence, and hematuria). Symptoms are often nonspecific, and, therefore, a high index of suspicion is required. In cases of mesh exposure, careful vaginal examination usually identifies an area on the anterior vaginal wall with separated epithelial edges and visible mesh. **The management of this complication is not standardized,** and there are various reports claiming successful outcomes with observation, partial sling excision, complete sling excision, and reapproximation of the vaginal mucosa over the exposed mesh (Table 125.9).

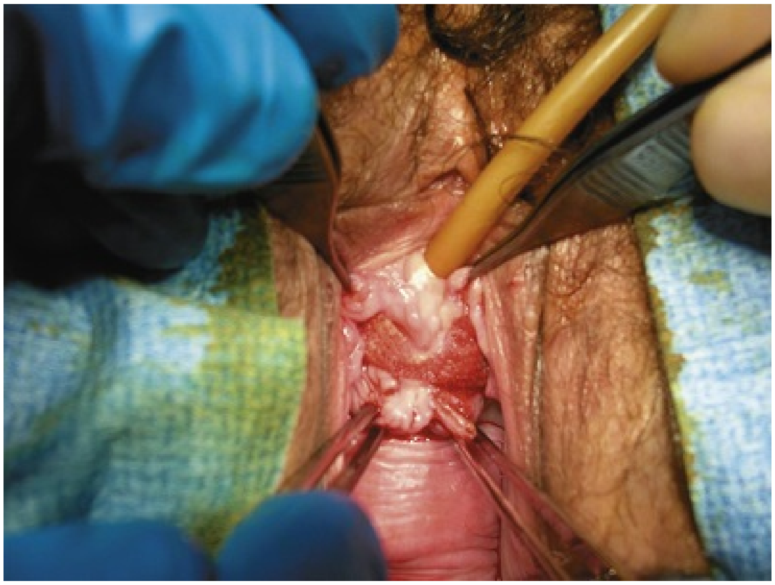

FIG. 125.12 Vaginal mesh exposure.

TABLE 125.9

Management of Vaginal Mesh Exposure

	TOTAL PATIENTS	CONSERVATIVE MANAGEMENT	FINAL MANAGEMENT	SYMPTOM RESOLUTION[a]	CON

[a] Most common presenting symptoms were vaginal pain, dyspareunia, palpable mesh, urinary tract infection, and vaginal discharge.

NR, Not recorded.

It appears that the material composition of mesh is particularly important in the event of mesh exposure. Domingo et al. (2005) reported a relatively high incidence of vaginal exposure in their series using either the ObTape or UraTape. They attributed their exposure rate to the characteristics of the particular mesh and, specifically, the reduced pore size among other mechanical properties of the mesh. The authors noted a slightly higher risk for exposure after the ObTape compared with UraTape (19% vs. 12%) and felt that this was most likely because of reduction in pore size and a higher degree of encapsulation. They also concluded that synthetic mesh with larger pore sizes facilitates vascular and tissue ingrowth, optimizing mesh incorporation. In this series, sling exposure was usually managed by removal through the transvaginal approach alone or in combination with a transobturator approach. Despite mesh removal, 78% of the women were continent. High rates of vaginal exposure (up to 15%) after ObTape or UraTape MUS have been reported by other authors (Al-Singary et al., 2007; Babalola et al., 2005; Deval et al., 2006; Dobson et al., 2007; Domingo et al., 2005; Giberti et al., 2007; Juma and Brito, 2007; Karsenty et al., 2007).

In a series of 17 vaginal exposures in an Australasian cohort, 35% were asymptomatic and identified by vaginal examination only (Hammad et al., 2005). Symptomatic women reported palpable mesh, vaginal discharge, local pain, UTI, and dyspareunia.

Newer, macroporous polypropylene slings have a much lower incidence of exposure and infectious complications (Lee et al., 2009; Neuman, 2007; Rechberger et al., 2009; Waltregny et al., 2008). Two groups reported no evidence of mesh exposure at 1-year (Lee et al., 2009) and 3-year (Waltregny et al., 2008) follow-up. Waltregny et al. (2008) reported one intraoperative vaginal sulcus laceration, which was closed uneventfully. Lee et al. (2009) proposed that a modified canal transobturator sling (creating a suburethral tunnel between two oblique lateral incisions in the anterior vaginal wall) decreases the incidence of vaginal exposure compared with the classic single midline incision. The value of this technique needs to be confirmed by a randomized trial. Chen et al. (2008) assessed risk factors for vaginal exposure that developed in 6 of 239 women (2.5%) after synthetic MUS and found that diabetic women were 8.3 times more at risk. These authors encourage counseling women with diabetes of the risk for exposure.

Management of Mid-Urethral Sling Mesh Exposure

Management of mesh exposure is within the scope of practice of most pelvic surgeons; however, mesh perforation of the bladder or urethra may require a tertiary referral. Some authors propose observing any exposure of mesh that is less than 1 cm because the area may heal spontaneously (Kobashi and Govier, 2003; Tijdink et al., 2011). Four women (one after TVT and three after SPARC) with vaginal exposure were treated in a conservative fashion (Kobashi et al., 1999). All women had serial physical examinations and spontaneously re-epithelialized by 3 months. The authors attributed their success to the macroporous characteristics of the polypropylene mesh, which facilitated excellent tissue ingrowth. Conservative management is less likely to be successful with older, less-used sling materials, such as Gore-Tex, polyethylene terephthalate, and silicone. **In general, small areas of mesh exposure should be treated with sequentially increasing invasiveness. The first treatment should involve observation and then the addition of conjugated estrogen and, possibly, antibiotic creams. The next step should be limited excision and trimming of the exposed mesh and reapproximation of vaginal epithelial edges. If these options fail, excision of most of the mesh from a transvaginal approach should be pursued in most cases.** Table 125.9 reviews the management of mesh exposure in the literature.

In a review by Huang et al. (2005), six vaginal exposures and one bladder perforation after polypropylene MUS were initially managed expectantly. In four women with exposure of less than 1 cm, conservative management was initiated for a 3-month period. One of these women was observed for 24 months without adverse sequelae. In contrast with the results seen by Kobashi and Govier (2003), none of the women in this review had vaginal epithelialization over the area of exposure. Therefore, all six underwent transvaginal mesh excision in conjunction with an excision of all fibrotic vaginal tissue. Symptoms resolved in all women, and all were continent at their last follow-up. Although all women ultimately required surgical intervention, the authors felt that a trial of conservative management in appropriately selected patients (i.e., exposure <1 cm) was reasonable, and, if no epithelialization occurs after 3 months of follow-up, the mesh should be surgically removed.

If conservative measures fail, the next step for intervention should be operative management and will ultimately depend on the surgeon's preference and the size of the exposure. In the series by Tijdink et al. (2011), only 6 of 48 women with mesh exposure (12.5%) had persistent exposure after partial mesh excision. **Operative management typically involves excision of the exposed mesh, undermining of vaginal mucosal flaps, thorough irrigation with antibiotic solution, and reapproximation of vaginal edges with delayed, absorbable sutures.** The addition of topical antibiotics and conjugated estrogen cream may, theoretically, improve tissue quality before pursuing surgical intervention.

In a review of mesh-related complications in 200 women, Tsivian et al. (2004) observed five vaginal exposures after MUS (Tsivian et al., 2004). Four women required surgical excision of the exposed mesh, and one asymptomatic woman was being treated conservatively without adverse outcomes. Exposure resolved in all women after partial mesh excision and judicious vaginal debridement.

In the Finish nationwide review of 1455 MUS procedures, 10 women had vaginal polypropylene sling exposure. Three were managed without surgical intervention with favorable results and maintained continence (Kuuva and Nilsson, 2002). Four women had the vaginal mucosa resutured over the exposed mesh, and two women required partial mesh excision. One was lost to follow-up, and her management was unknown at the time of their report. According to this national registry, continence was maintained in all women regardless of management. Among 166 MUS surgeries performed by Giri et al. (2007), five women (3%) developed vaginal exposure 4 to 40 months postoperatively. Women reported vaginal discharge, pain, bleeding, and dyspareunia. In the operating room, the eroded margin of vaginal mucosa was trimmed and closed over the mesh. All of the women were subsequently symptom free at 12-month follow-up.

Ordorica et al. (2008) reported on 11 vaginal exposures after nonautologous sling placement (33 retropubic, 2 with bone anchors, 3 transobturator). In all cases, the involved sling and sutures were excised; however, the bone anchors were unable to be removed. An autologous sling was placed in the same setting if the woman complained of SUI at presentation. Two women had recurrent or persistent SUI, two had de novo urgency or frequency, and one developed osteitis pubis.

Kuhn et al. (2009b) used a validated questionnaire to determine the sexual function of women after correction of MUS exposure (Female Sexual Function Index [FSFI]). Among 21 exposures, 3 healed with topical estrogen, and 18 women with larger defects required operative intervention. Two women developed recurrent exposure after initial vaginal closure failed, with one undergoing repeat vaginal closure and the other having partial sling excision and closure. The domains of desire, arousal, lubrication, satisfaction, and pain improved significantly, and orgasm remained unchanged.

Key Points: Mid-Urethral Sling Mesh Exposure

- Conservative management is a plausible option in well-selected patients who are relatively asymptomatic and have small-caliber exposures (<1 cm). Favorable results have also been observed in selected patients with vaginal advancement flaps and suture approximation of the debrided vaginal mucosa over the exposed mesh.
- Even with partial excision of the mesh, continence is maintained in the majority of women.
- Observation should never be considered when there is urethral or intravesical perforation. More data supporting specific management strategies are necessary before a given approach can be advocated for patients with this complication.
- We recommend initial judicious observation for small vaginal exposures and, when appropriate, addition of topical conjugated estrogen cream. Excision should be reserved for failure of conservative therapy or when local symptoms, such as bothersome dyspareunia, mitigate against observational management.

Mid-Urethral Sling Trocar Injury to the Urinary Tract

In the majority of the literature, results listed for perforation (or injury) of the bladder or urethra refer to trocar passage into the urinary tract at the time of surgery. In these studies, the trocar injury is recognized at the time of surgery, and the trocar is passed again safely with continuation of the surgical case. **Trocar injury is generally considered to be a benign condition, and no study has shown a link between trocar injury and perioperative hemorrhage, hematomas, or subsequent mesh perforation of the bladder or urethra.** Because of the nature of trocar passage, **the rate of trocar injury is generally lower with transobturator MUS. In randomized trials, the rate of bladder or urethral trocar injury at the time of retropubic MUS falls between 2.7% and 23.8%** (Andonian et al., 2005; Porena et al., 2007).

Although initial reports described the risk with the transobturator MUS approach as being negligible, the rate of bladder or urethral trocar injury at the time of transobturator MUS surgery in randomized studies falls between 0% and 1.3% (Porena et al., 2007; Richter et al., 2010). Minaglia et al. (2004) reported three cases of intraoperative bladder injury while performing the transobturator insertion method. They identified all injuries intraoperatively because of their use of cystoscopy as an adjunct to all insertion procedures. All injuries were managed with catheter placement for 1 week postoperatively, and these authors noted no complications after sling removal and reinsertion at that same setting. It is possible that bladder trocar injuries are more likely to occur with out-to-in transobturator slings. With 10 of 11 bladder injuries occurring with the out-to-in technique in their study, Tamussino et al. (2007) concluded that trocar injury was more likely with this method.

Urethral Perforation During Mid-Urethral Sling Mesh Placement

Urethral perforation is defined as presence of sling material within the urethral lumen (Fig. 125.13). **The incidence of urethral perforation after MUS (transobturator and retropubic) surgery was 0% to 0.6%, respectively, in a review of randomized prospective and large retrospective studies (see** eTable 125.8). **Factors thought to contribute to urethral perforation include compromised urethral blood supply (e.g., from radiation therapy or estrogen deficiency), excessive sling tension, extensive dissection in close proximity to the urethra with subsequent urethral devascularization, iatrogenic urethral injury at time of device insertion, and traumatic urethral dilation. Furthermore, twisting or rolling of the sling can create a ridge that leads to pressure necrosis and perforation through the urethra** (Dell and O'Kelley, 2005). **Management of this complication is extremely challenging** and may be associated with significant morbidity, because access to the sling is traditionally gained by incising the urethra. Endoscopic management has been described, but medium- and long-term outcomes are unknown.

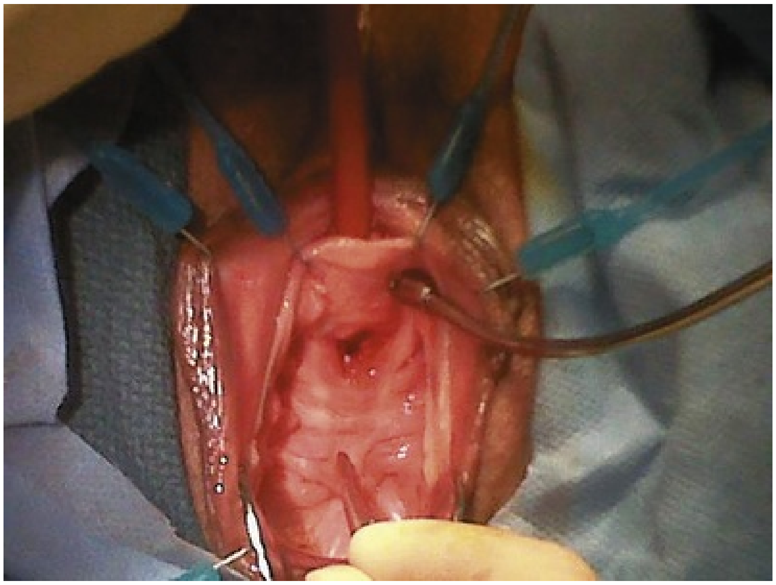

FIG. 125.13 Urethral mesh perforation and urethrovaginal fistula.

Instances of urethral perforation are rarely asymptomatic and **typical presenting symptoms** include urgency, UUI, obstructive voiding, urinary retention, recurrent UTI, and persistent urinary incontinence (Glavind and Sander, 2004; Haferkamp et al., 2002; Lieb and Das, 2003; Madjar et al., 2002; McLennan, 2004; Pit, 2002; Sweat et al., 2002; Tsivian et al., 2004; Vassallo et al., 2003; Wai et al., 2004). There is often a history of CIC and postoperative urethral dilations, and diagnosis is often delayed in these women for an extended period. In a review by Amundsen et al. (2003), the average time from placement of the initial PVS to diagnosis of urethral perforation was 9 months.

Confirming the presence of mesh within the urethral lumen during cystoscopy is diagnostic. Voiding cystourethrography has also been useful adjunctively by documenting a dilated proximal urethra related to high-grade obstruction caused by the eroded sling (Lieb and Das, 2003). A review of urethral perforation management is presented in Table 125.10.

[a] Most common presenting symptoms were urinary tract infection, urethral obstruction, urge urinary incontinence, pain, incontinence, urgency, dysuria, and hematuria.

MUS, Mid-urethral sling; *NR,* not recorded; *PVS,* pubovaginal sling.

Nine urethral perforations (0.6%) were reported in the Australasian database, with 89% being symptomatic and 30% manifesting greater than 1 year after surgery (Hammad et al., 2005). Presenting symptoms included urinary retention, bleeding, and local pain, and one case was discovered incidentally on cystoscopy. Unlike the reported vaginal exposures, 33% of the urethral perforations occurred when the polypropylene sling procedure followed another anti-incontinence procedure. Four (44%) were managed nonoperatively, as two of these women were too frail to undergo operative intervention. Five women (56%) had transvaginal excision, and all five were cured and dry postoperatively.

Management of Mid-Urethral Sling Mesh Perforation of the Urethra

Several studies have reported the successful treatment of urethral mesh perforation endoscopically (see Table 125.10). **Although we prefer transvaginal surgical excision as a first-line treatment, endoscopic management of small areas of mesh perforation appears to be a reasonable initial option based on a review of the literature. If endoscopic treatment fails, the next step in management of urethral perforation typically involves transvaginal urethrotomy and excision of the perforated mesh. An autologous fascial sling or a Martius labial fat pad graft can be used at the discretion of the surgeon.**

For endoscopic management, McLennan (2004) successfully managed an MUS urethral perforation by using hysteroscopic scissors to transect the mesh flush with the urethral mucosa. Catheter drainage was continued postoperatively for 72 hours. The woman remained symptom-free and continent at 10 months of follow-up. Wijffels et al. (2009) used an endoscopic transurethral approach successfully in three cases of urethral perforation. The visible mesh was grasped with forceps and cut while on traction with scissors on both sides of the urethra. One woman had recurrent SUI and subsequently underwent placement of another MUS. Baracat et al. (2005) successfully used a similar approach for five urethral perforations.

In our opinion, although it is relatively easy to remove a small portion of perforated mesh with endoscopic scissors or to ablate the mesh with a holmium laser, these women are likely to experience recurrence and require further surgeries. Endoscopic excision does not release the tension on the mesh that may be contributing to the perforation and does not provide any interposing tissue. **For surgical excision, we will often remove the mesh so that it is no**

longer in close proximity to the bladder or urethra and no longer under tension. The approach and type of incision depend on the location of the perforation.

Other authors have described transvaginal excision of perforated mesh. Pit (2002) described the management of two cases of urethral perforation by incising the urethra and cutting the mesh at the level of the mucosa. The mesh was then dissected on its medial edge toward the inferior ischiopubic ramus and cut bilaterally, which allowed the mesh to be removed from the periurethral fascia. A Martius graft was placed over the urethra in one case, and a cadaveric fascia lata graft was used in the second. A second MUS was then placed over the tissue bolsters without complication.

Glavind and Sander (2004) reported a urethrovaginal fistula caused by polypropylene mesh urethral perforation. Transvaginal mesh excision failed to resolve the fistula, and the woman required two transabdominal fistula repairs until closure and symptom resolution occurred. Persistent SUI was subsequently managed by conservative means with satisfactory results. Sokol and Urban (2008) reported use of the internal urinary sphincter for covering the defect after sling resection. They suggested that this may reduce the risk for fistula formation and be a less morbid option than a Martius flap. Four additional case reports reported excellent results with use of a midline transvaginal approach with partial mesh excision and closure of the urethra (Haferkamp et al., 2002; Lieb and Das, 2003; Madjar et al., 2002; Wai et al., 2004). The postoperative outcomes reported by each group were excellent, with all women achieving symptom resolution after surgical intervention. In two women, mild recurrent SUI was successfully managed with biofeedback (Glavind and Sander, 2004; Wai et al., 2004). In two women, continence was achieved with an intraoperative fascial sling, and, in a single case, a staged fascial sling resulted in satisfactory continence (Vassallo et al., 2003; Wai et al., 2004). It is important to note that, despite effective healing of the urethra after mesh removal, eventual incontinence and inadequate symptom resolution may occur (Kowalik et al., 2018). Long-term follow-up and additional treatment options are warranted in this population.

During surgical intervention for slings that perforate into the urethra, we prefer an inverted-U incision because this allows for excellent exposure of the proximal urethra, bladder neck, and endopelvic fascia. Likewise, this incision provides a vaginal epithelial flap that avoids overlapping suture lines, theoretically decreasing the risk for a fistula. The distal portion of the inverted U should be distal to the site of the urethral perforation, and the proximal portions of the U should extend to the level of the bladder neck in most cases. **We will frequently use a Martius labial fat pad flap to further prevent fistula formation. An autologous PVS is routinely placed if dissection of the sling out of the urethra creates a large defect or a defunctionalized urethra. Mesh excision is typically carried out to the level of the pubic bone or ischiopubic rami.** This type of excision leaves behind the arms of the mesh that tunnel into the retropubic space or obturator fossa. It is not typically necessary to enter these spaces because the mesh at this location is no longer under tension and is far from the urethra. We typically leave a Foley catheter for 3 weeks after repair of the urethra.

Mid-Urethral Sling Mesh Perforation of the Bladder

The finding of synthetic mesh within the lumen of the urinary bladder is a rare, but distressing complication (Fig. 125.14; Table 125.11). **The incidence falls between 0.5% and 0.6%** (Kuuva and Nilsson, 2002; Ward and Hilton, 2002)**. The majority of intravesical mesh perforations are most likely the result of an unrecognized cystotomy or placement of the mesh within the urinary bladder at the time of surgery.** True migration of the mesh across the seromuscular wall of the bladder into the lumen is much less likely, and this **underscores the importance of performing a complete and thorough cystoscopic examination of the bladder with adequate hydrodistention to minimize this complication.** We have found that the trocar may sometimes telescope the bladder wall during insertion and obscure visible bladder perforation.

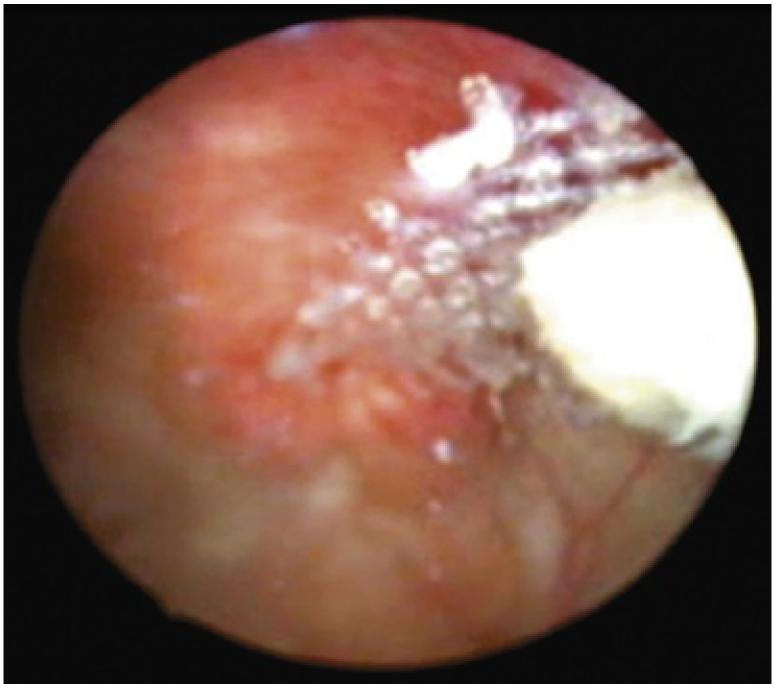

FIG. 125.14 Cystoscopic view of intravesical retropubic sling perforation.

[a] Most common presenting symptoms were urinary tract infection, urge urinary incontinence, pain, incontinence, urgency, hematuria, bladder stone, and dysuria.

[b] Includes one patient who had an I-Stop out-to-in transobturator mid-urethral sling.

[c] All were TVT-Secur slings.

NR, Not recorded.

Women with MUS bladder perforation typically report a variety of **symptoms.** A review of seven reported cases in the literature by Negoro et al. (2005) found that the typical symptoms are lower abdominal pain, intermittent gross hematuria, recurrent UTI, urgency, frequency, dysuria, and urinary incontinence. Diagnosis is made by cystoscopic examination of the bladder. Imaging modalities such as computed tomography scans and cystography may help in difficult cases but are not a substitute for cystoscopic examination.

Theoretically, transobturator slings should have a lower rate of mesh perforation into the bladder than retropubic slings; however, intravesical mesh perforation after transobturator MUS and cystocele repair has been reported (Parekh et al., 2006). The woman did not undergo cystoscopy intraoperatively. She initially had mesh on the left side of the bladder, then 6 months later had sling material on the right side of the bladder. She underwent a successful transurethral, transvaginal, and suprapubic mesh resection.

Management of Mid-Urethral Sling Mesh Perforation of the Bladder

Observational treatment is not recommended for mesh perforation of the bladder because the mesh often becomes encrusted, leading to stone formation, persistent lower urinary tract storage and voiding symptoms, recurrent UTIs, and intermittent gross hematuria. Different techniques and surgical approaches have been advocated with varying levels of invasiveness, complexity, and success.

For small areas of mesh perforation, the literature supports endoscopic excision with scissors or ablation with the holmium laser as an appropriate initial step. In 14 women with intravesical mesh, Oh and Ryu (2009) transurethrally resected the mesh deep into the perivesical fat. The women had dysuria, hematuria, pelvic pain, and urgency preoperatively, and six women had stone encasing the mesh at the time of transurethral excision. With a mean follow-up of 18 months, 13 (93%) had no recurrence. One woman had recurrent bladder stones, and one had mild SUI and UUI, which were controlled with anticholinergics. No further treatment for SUI was performed.

In a case report, Jorion (2002) excised the mesh endoscopically using an offset nephroscope transurethrally and a 5-mm laparoscopic trocar placed suprapubically. Laparoscopic grasping forceps were used to grasp the mesh, and endoscopic shears excised the mesh flush with the bladder mucosa, allowing for easy mesh removal. Cystoscopy at 1 month revealed healed mucosa, and the woman was continent and symptom-free. In another report, the mesh was initially cut endoscopically, but because of an adherent calculus, the mesh could not be extracted endoscopically (Tsivian et al., 2004). Therefore, a suprapubic approach was required to remove the stone and intravesical mesh.

Holmium:yttrium-aluminum-garnet (Ho:YAG) laser excision (or vaporization) of encrusted intravesical MUS has been used successfully in several cases (Baracat et al., 2005; Giri et al., 2005; Hodroff et al., 2004; Huwyler et al., 2008; Lane et al., 2005; Shrotri et al., 2010). Since stones frequently form on the intravesical portions of the sling, Irer et al. (2005) and Mahmoud and Wadie (2007) described successful endoscopic laser lithotripsy of the calculi and transurethral resection of the sling material. **We reserve endoscopic (holmium laser) management of intravesical mesh perforation for very small areas of perforation in select patients.**

If endoscopic excision is attempted and fails, removal of perforated bladder mesh can be removed through a transvaginal or retropubic approach. For slings that perforate into the bladder at or below the trigone, we prefer an inverted-U incision similar to the aforementioned management of urethral perforation because this allows for exposure of the proximal urethra, bladder neck, and endopelvic fascia. Furthermore, this incision provides a vaginal epithelial flap that avoids overlapping suture lines, theoretically decreasing the risk for fistula. Similar to the management of urethral perforations, we do not excise the entire sling as long as it is no longer under tension and is well away from the bladder.

For slings that perforate the bladder dome or other areas of the bladder not accessible from a transvaginal approach, we remove the mesh transabdominally. The sling can usually easily be seen entering the bladder in the retropubic space. Although not always necessary, opening the bladder in the midline usually aids with closure and identification of the exact area of bladder perforation. **In general, reconstruction should involve nonoverlapping suture lines and may benefit from interposition of tissue such as a labial fat pad, greater omentum, peritoneum, or autologous fascial sling.**

In a report by Negoro et al. (2005), a retropubic approach was used to resect the intravesical portion of the mesh. The bladder was closed with absorbable suture, and catheter drainage was maintained postoperatively. The woman was symptom free and continent at 10-month follow-up. Volkmer et al., (2003), Sweat et al. (2002), and Huang et al. (2005) used a combined transvaginal and abdominal approach to remove the sling in its entirety. One woman had residual urgency and frequency treated with anticholinergics, and three women had resolution of symptoms but recurrent SUI. One woman was managed with periurethral collagen injection, and two underwent pelvic floor muscle training and estrogen.

There are several reported cases of successful laparoscopic removal of intravesical mesh after retropubic sling placement. One of these cases used a three-port intraperitoneal approach (Siow et al., 2005), and the other two used a three-port extraperitoneal approach (Rehman et al., 2008). All of the women were symptom free and dry after the mesh removal. **The authors have also had success with an intraperitoneal robotic-assisted approach in women with bladder dome or posterior wall perforation.**

Key Points: Mid-Urethral Sling Mesh Perforation of the Urethra and Bladder

- Overall, the incidence of urethral and bladder mesh sling perforation is extremely low in the MUS literature.
- As the number of synthetic MUS surgeries continues to increase, physicians need to be mindful of the potential complications, have a high index of suspicion, and be aware of the management options available to treat the woman with urinary tract perforation.
- Conservative observational treatment is not an option for urethral and bladder mesh perforation.
- At the present time, transvaginal (or transabdominal) excision of the mesh with closure of the urethrotomy or bladder is our preferred first-line treatment in most cases of urethral and bladder perforation.
- If the repair is tenuous, a vascularized Martius labial fat pad graft can bolster the repair. Furthermore, an autologous fascial sling can be placed at the time of surgery to augment the repair or in a delayed fashion to treat recurrent SUI.

Infection and Pain After Mid-Urethral Sling Surgery

Groin and suprapubic pain are potential sequelae after MUS. Thigh and groin pain appear to be more commonly associated with the transobturator approach. A randomized controlled study from Finland revealed that 16% of women in the transobturator (in-to-out) group had groin pain compared with only 1.5% of those who underwent retropubic MUS (Laurikainen et al., 2007). In addition, groin pain may persist for a longer period after the transobturator MUS (Daneshgari et al., 2008). Long et al. (2009) and Wang et al. (2009) also found that women in the transobturator group have significantly more postoperative groin and thigh pain. Doo et al. (2006) noted persistent suprapubic pain in three (2%) women at 5-year follow-up after a retropubic MUS. In the Cochrane systematic review, Ford et al. (2017) estimated the rate of groin pain after transobturator MUS to be 6.4% from 18 trials involving 3221 women.

de Leval (2003) reported that 16% of women after transobturator MUS surgery had temporary groin pain that resolved after the second postoperative day. Similarly, Krauth et al. (2005) reported 14 cases (2%) of postoperative perineal and groin pain after transobturator MUS surgery, but also noted it to be transient and responsive to nonsteroidal anti-inflammatories in all but one case. The authors hypothesized that the cause of the pain was either subclinical hematoma or a transient neuropathic phenomenon. A randomized controlled trial by Teo et al. (2011) comparing the retropubic and transobturator MUSs was aborted because of a 26% incidence of leg pain in the transobturator MUS group (compared with 1.7% after retropubic MUS).

Fortunately, chronic groin and leg pain is an uncommon complication after MUS surgery. Roth (2007) found that steroids and local anesthetic were effective for pain relief with no side effects in three women with persistent groin pain 3 months postoperatively. Wolter et al. (2008) reported a case of refractory medial thigh pain after transobturator MUS, which ultimately required medial thigh and transobturator exploration by orthopedic surgery and sling excision.

Wound-related complications include **minor superficial cutaneous infections and pelvic abscesses.** Ward and Hilton (2002) found a 2% rate of vaginal wound infection after retropubic MUS, and Richter et al. (2010) found a 0.7% rate of vaginal wound infection in both the retropubic and transobturator MUS arms. Connolly (2004) reported a case of necrotizing fasciitis in an obese, diabetic woman that resolved after intensive resuscitation. It is interesting to note that a review of necrotizing fasciitis in gynecologic surgery found that obesity (88%), hypertension (65%), and diabetes (47%) were all risk factors for postoperative fasciitis (Gallup et al., 2002).

Fortunately, severe infection is a rare complication after MUS surgery; however, the diagnosis of this complication is variable and can be delayed by up to several years (Choi et al., 2011; Yenilmez et al., 2013). Mahajan et al. (2006) reported one case of failed sling and vaginal exposure that was associated with severe groin pain, fever, and chills 10 days postoperatively. The sling was easily removed through a vaginal incision, and mesh cultures were positive for *Bacteroides fragilis.* Complete symptom resolution occurred within 1 week of mesh removal. Abscesses and adductor myositis have also been reported, manifesting as leg pain, difficulty ambulating, and cellulitis (DeSouza et al., 2007; Goldman, 2006; Karsenty et al., 2007; Leanza et al., 2008; Zumbé et al., 2008). Gamé et al. (2004) reported an infected obturator hematoma after placement of an ObTape sling that required exploration and drainage. ObTape is no longer available for implantation. In general, severe infectious complications appear to be more common with the older, non–loosely woven polypropylene slings (Babalola et al., 2005).

Management of Severe Infection or Pain After Mid-Urethral Sling

In most cases, postoperative groin or leg pain after MUS can be managed with nonsteroidal anti-inflammatory medications, rest, and even physical therapy. Duckett and Jain (2005) reviewed different strategies for managing groin pain after retropubic MUS or similar MUS procedures in five women. Initial conservative management was successful in most women, with four women with persistent or severe pain treated with a combination of steroid and local anesthetic injections. Two women developed recurrent pain and had significant pain relief after sling excision. Medial thigh pain is a common problem after transobturator MUS surgery and, as with retropubic MUS, can usually be managed conservatively. A prospective study of 100 women who underwent transobturator MUS revealed a 24.4% incidence of early groin pain; however, the incidence of persistent groin pain 12 months after surgery after conservative management was only 3.7% (Lim et al., 2006).

In instances of chronic pain and severe infection after mesh MUS, and failure of nonoperative therapy, it may be necessary to attempt a complete mesh excision from both sides of the bone. In the case of retropubic mesh, this involves an abdominal and vaginal incision, and in the case of transobturator mesh, this involves incisions in the medial thigh and vagina. **For the complete excision of transobturator mesh, we typically consult an orthopedic surgeon**

to aid with lateral dissection of the sling. Reynolds et al. (2012) published their results with chronic groin pain after transobturator MUS that necessitated mesh excision from the obturator foramen. Five of the eight women were cured of their pain after a median follow-up of 8 months.

Voiding Dysfunction After Mid-Urethral Sling Surgery

Voiding dysfunction is a common problem after MUS surgery. **These voiding symptoms are typically the result of obstruction from the sling being placed too tightly, in the wrong location (too proximally), or associated with POP (unrecognized preoperatively or de novo). However, some women may have voiding dysfunction without evidence of obstruction.** Based on anecdotal experience after removing hundreds of chronically obstructive slings, we have found that obstructive slings are most likely to be found close to the bladder neck. In addition, we have found that progression of anterior and apical prolapse can cause a nonobstructive sling to become obstructive 10 years or more after placement of the sling. If the diagnosis of sling obstruction is in doubt, urodynamics can be performed to provide confirmation (Levin et al., 2004; Volkmer et al., 2003). Although most cases of voiding dysfunction after MUS surgery are the result of sling obstruction, not all women will have obstruction on urodynamic evaluation. Table 125.12 displays a literature review of the management of voiding dysfunction after MUS surgery.

TABLE 125.12

In general, the rates of de novo urgency and perioperative urinary retention are similar among the different types of MUS. The most common symptoms of obstruction are an inability to void (urinary retention), incomplete emptying, and de novo urgency and frequency. The urinary storage symptoms and pain become more prevalent over weeks to months as the bladder attempts to adjust to the obstruction. **The optimal evaluation for women with postoperative voiding dysfunction is poorly defined in the literature. The decision to perform urethrolysis or sling incision is usually based on a clear temporal relationship between onset of symptoms and the surgical procedure.** Urodynamic studies can be useful in selected cases at the physician's discretion. However, it appears that the temporal relationship correlating symptoms with an antecedent surgical procedure should be the primary criterion in selecting women for sling-release procedures. **Cystoscopy is useful to rule out bladder pathology, urethral mesh perforation, and a hypersuspended bladder neck.**

In older, nonrandomized studies, there did not appear to be a significant difference in postoperative voiding dysfunction between retropubic and transobturator MUS surgeries (de Tayrac et al., 2004; Mansoor et al., 2003). More recently, Nguyen et al. (2012) cited rates of sling incision or loosening to be 1.2% and 1.9% after retropubic MUS and TOT, respectively. **However, in a more recent randomized controlled trial by Richter et al.** (2010)**, there was a significantly higher rate of voiding dysfunction necessitating surgery (or permanent catheterization) after a retropubic MUS compared with transobturator MUS (2.7% vs. 0%).** The rate of urinary retention (defined as catheterization for greater than 6 weeks) was also higher in the retropubic MUS group (3.7% vs. 0.7%). Another study evaluating 188,000 MUS surgeries with follow-up of up to 9 years cited a sling revision or removal rate of 1.3% (Jonsson Funk et al., 2013).

When selecting women for the retropubic MUS procedure, it might be helpful to identify preoperative factors predictive of postoperative voiding dysfunction and urinary retention. In a study by Hong et al. (2003), 32 of 375 women (8.5%) required catheterization for greater than or equal to 72 hours after surgery. Twenty-eight of these women resumed normal voiding within 3 months, and 4 women required a transvaginal sling release. On multivariate analysis, only peak flow rate predicted urinary retention. In 2004, a small study of 14 patients showed that low detrusor pressure at maximum flow (PdetQmax) on a preoperative pressure-flow study correlated with elevated PVR urine in three women who had retropubic MUS (Kawashima et al., 2004).

Tsivian et al. (2009) found that women having transobturator MUS alone had no voiding dysfunction postoperatively, whereas seven (11%) of those who had undergone additional pelvic surgery experienced voiding dysfunction. However, Sokol et al. (2005) did not find this same trend in a similar cohort undergoing retropubic MUS. The median time to voiding (8 days vs. 5 days) and rate of urinary retention were similar between women with and without POP repair. However, increasing age, decreasing BMI, and postoperative UTI were independent predictors of increased time to adequate voiding. Previous history of anti-incontinence surgery was the only independent variable predictive of urinary retention. In summary, **there does not appear to be a consensus in the literature regarding preoperative factors that contribute to voiding dysfunction after MUS surgery.**

Management of Voiding Dysfunction After Mid-Urethral Sling Surgery

Urinary obstruction after MUS surgery is frequently transient and can be managed with short-term CIC, although occasionally symptoms mandate sling release. Long-term retention after retropubic MUS surgery is a rare complication. In these cases, removal or incision of the sling usually improves the woman's symptoms.

In most cases, postoperative voiding dysfunction can be successfully treated conservatively. In the literature, temporary indwelling catheter drainage, CIC, timed voiding, biofeedback, PFMT, and selective medical therapy have all been successful to some degree in managing postoperative voiding dysfunction. In the Kuuva and Nilsson (2002) analysis of the Finnish database, 20 of 34 women with urinary retention resumed a normal voiding pattern after less than 14 days of conservative management. However, two women took an additional 5 and 6 weeks to return to normal voiding. Only one of the 34 women required midline sling lysis with subsequent normal voiding. Also in that study, there were 111 women with voiding dysfunction but no urinary retention. Thirteen of these women had voiding dysfunction that lasted up to 4 months, and two women required surgical transection of the sling to achieve a normal voiding pattern

(Kuuva and Nilsson, 2002, 2003). Pharmacotherapy with α-adrenergic antagonists may decrease bladder outlet resistance enough to relieve minimal or mild BOO without more invasive therapies (Patel et al., 2012).

Several reports have shown some benefit of urethral dilation or loosening the sling under anesthesia (Hong et al., 2003; Klutke et al., 2001; Mishra et al., 2005; Ozel et al., 2004). Mishra et al. (2005) performed urethral dilation in 3 of 52 women who had retention 3 months after MUS, and two of the three voided effectively after urethral dilation. In this series, the postoperative retention rate was significantly higher (23%) than in other published data. There are concerns about the potentially traumatic nature of dilation, which could induce scarring of the urethra or lead to mesh perforation. **It is our opinion that urethral dilation may be detrimental to the urethra and should not be performed.** Formal sling loosening may be performed by opening the vaginal incision and placing a right-angle clamp between the sling and urethra. Downward traction on the sling for 1 to 2 cm may lead to a significant improvement in greater than 95% of obstructed patients (Rautenberg et al., 2014). It must be noted that this technique is optimal when performed early in the postoperative period before tissue ingrowth takes place (Brucker and Malacarne, 2016).

Several methods of sling incision have been described in the literature, including lateral and bilateral approaches (Tran and Rutman, 2018). **Cutting the MUS in the midline through a single vertical vaginal incision is the preferred method to manage persistent voiding dysfunction that results from an obstructive sling within the first 3 months after surgery.** Compared with autologous PVS, in our opinion, the MUS after 3 months is fixed along its entire course, and midline sling incision may not achieve enough sling relaxation to resolve voiding dysfunction. In these cases, we perform a more formal sling excision and urethrolysis similar to that described earlier for sling excision after perforation.

Reassuringly, studies by Laurikainen and Killholma (2006), Gamé et al. (2006), Clifton et al. (2014), and Klutke et al. (2001) found that 50%, 70%, 79%, and 94% of women, respectively, remained continent after sling lysis. In the large review by Klutke et al. (2001), 17 of 600 women (3%) required reoperation secondary to urinary retention and persistent obstructive symptoms after retropubic MUS. In their series, sling release was performed at a mean of 64 days after MUS surgery. The sling was identified and either released with downward traction for 1 cm or cut in the midline. There was one urethral injury, which was repaired without sequelae. After sling release, symptoms resolved in all women, all women voided to completion, and 16 woman remained continent. In a nationwide retrospective review of 9040 women who had MUS, approximately 50% of the 48 women who required sling lysis were cured of their voiding dysfunction and remained continent (Laurikainen and Killholma, 2006). However, 4 (8.3%) continued to have retention after lysis. There was no difference in continence rates based on interval between MUS placement and sling lysis. Repeat sling lysis or urethrolysis was used to treat refractory retention. Lastly, Gamé et al. (2006) presented results of 30 women who required sling lysis with a lateral sling incision over a 4-year period, of whom 70% remained continent.

Zubke et al. (2004) managed three women with urethral obstruction after MUS surgery by using a novel surgical technique. They cut the sling in the midline with a transvaginal approach and sutured the edges of the sling to a polypropylene mesh, thus lengthening the sling. All three women were continent and resumed normal voiding after intervention.

The exact timing of sling incision varies in the literature; however, most authors recommend waiting at least 2 weeks (Glavind and Glavind, 2007; Long et al., 2004) before sling incision in cases of urethral obstruction. Even though Kuuva and Nilsson (2002) reported return to normal voiding after 6 weeks of conservative management, the majority of studies do not support waiting more than 4 weeks. **In our opinion, in cases of significant obstruction or retention, the sling should be incised within 4 weeks of surgery.** Also, in our experience, even though some women may return to "normal voiding" with conservative management, they often have persistent urgency and frequency.

Key Points: Mid-Urethral Sling Voiding Dysfunction

- Based on the available data, it appears that long-term urinary retention and obstructive voiding dysfunction are both rare after the MUS procedure.
- Although definitions of urinary retention and indications for management vary in the reported literature, most patients may be initially managed conservatively.
- Anecdotal cases have shown modest benefit from urethral dilation.
- For patients with persistently elevated residual urine and bothersome symptoms refractory to conservative management, transvaginal sling

release procedures consistently provide resolution of symptoms with maintenance of continence in the majority of women. We recommend a waiting period of at least 2 to 4 weeks before sling release.

- Sling release should be attempted through a small midline vaginal incision using minimal dissection.

Sexual Dysfunction After Mid-Urethral Sling Surgery

Varying degrees of sexual impairment have been reported after MUS surgery, with rates approaching 20% in some studies. In the study by Mazouni et al. (2004), 71 women were prospectively followed after they underwent retropubic MUS. In this study, 55 women had no sexual impairment before surgery, 14.5% of the women developed dyspareunia, and 5.4% experienced decreased libido after surgery. However, in a more recent study of 1112 women by Stav et al. (2010b) not designed to specifically look at sexual dysfunction, the rate of de novo dyspareunia after MUS was only 3%.

Marszalek et al. (2007) performed a cross-sectional analysis and noted that a 14.3% deterioration in sexual function was significantly associated with de novo urgency, dyspareunia, and the sensation of incomplete emptying. In 2008, Demirkesen et al. (2008) compared sexual satisfaction after MUS surgery and Burch colposuspension. In that study, 54% expressed a negative change, with most reporting dyspareunia. The MUS appeared to more adversely affect sexual satisfaction, but the difference was not significant. Kuhn et al. (2009a) reviewed the impact of sling removal on postoperative female de novo dyspareunia and found that the pain improved significantly.

There is also evidence that treatment of urinary incontinence can improve sexual function after surgery. In the randomized trial by Ward and Hilton (2008), the rate of dyspareunia actually decreased from 34% preoperatively to 13% 5 years after sling surgery. In 2009, Bekker et al. (2009) published the results of a retrospective evaluation of sexual function in 136 women after MUS surgery. The authors found that 21.3% of women reported improved sexual intercourse after surgery, and 5.9% reported worsened sexual intercourse. The authors mostly attributed the improved sexual function to a significant decrease in coital incontinence.

Other Complications After Mid-Urethral Sling Surgery

A diverse group of complications have been reported with the MUS, in addition to those mentioned previously. These include infection, bleeding, vascular injury, bowel perforation, and death. UTI is probably the most common and easily treatable complication of MUS surgery. Rates of UTI after MUS surgery range from 22% to 31% in large randomized trials (Richter et al. 2010; Ward and Hilton, 2002). In a retrospective review of the National Surgical Quality Improvement Program (NSQIP) database of 9,022 MUS surgeries from 2006 to 2014, Vigil et al. (2017) cited a UTI incidence of 2.6%. Factors independently associated with an increased infection risk included age older than 65 years (OR 1.54, 95% CI 1.07 to 1.22), BMI greater than 40 kg/m^2 (OR 1.89, 95% CI 1.23 to 2.92), and hospital admission (OR 2.06, 95% CI 1.37 to 3.11). MUS surgery performed by urologists carried a reduced risk for infection compared with the surgery performed by gynecologists (OR 0.52, 95% CI 0.40 to 0.69).

Another less common complication is intraoperative and postoperative **bleeding.** This complication is usually inconsistently reported in the literature. A review of the literature reveals that **severe bleeding or hematoma occurs in approximately 2% to 3% of women and can usually be managed with observation or local compression** (see eTable 125.8). This table also shows that in 8 of 10 studies comparing different MUS approaches, bleeding complications occurred more commonly after retropubic MUS. In their study, Wei et al. (2012) found the average estimated blood loss after MUS to be 156 mL. In 2004, Flock et al. (2004) reported that 4.1% of 249 women experienced a hemorrhage of 300 mL or more and required surgical intervention after retropubic MUS. Tseng et al. (2005) performed ultrasonography on all 62 women after MUS and found that 8 (12.9%) women had significant retropubic hematomas greater than 5 cm on the day after surgery. Only one patient required hematoma evacuation, and, in the remainder, repeat ultrasonographic examinations 1 month after surgery revealed that the hematomas had resolved. **Of interest, this study revealed that a postoperative hematoma may be a relatively common asymptomatic event after trocar passage.**

Serious complications such as vascular perforation, intestinal perforation, or even death remain extremely rare. The rate of serious vascular complications in the Finnish registry was 0.07% (Kuuva and Nilsson, 2002). Comparably, the Austrian registry reported a bowel perforation rate of 0.04% (Tamussino et al., 2001). In 2007, Deng et al. (2007) reviewed the complications reported to the FDA MAUDE database. The authors found that of 928 reported complications, 161 were considered major. The major complications included 39 vascular injuries, 38 bowel injuries, and 10 deaths.

Management of Recurrent or Persistent Stress Urinary Incontinence After Mid-Urethral Sling Surgery

Persistent SUI (no dry period after MUS) after otherwise routine MUS surgery may be caused by poor surgical technique, wrong choice of procedure, or suboptimal patient selection. On the other hand, recurrent SUI (SUI resolved, but then recurred) is thought to occur most commonly because of various patient-associated factors, such as age, obesity, concomitant preoperative UUI, and postoperative change in POP. The exact length of time separating persistent and recurrent post-MUS SUI is not clear, but the chance of undergoing repeat surgery is estimated to be 6% (Zimmern et al., 2016).

The evaluation of women with persistent or recurrent SUI is much like that of a woman being considered for primary anti-incontinence surgery. A focused history and pelvic examination should be performed to evaluate urethral mobility and the presence of POP. A urinalysis and PVR should be performed, and cystoscopy should be strongly considered for women with concomitant OAB symptoms or hematuria. Furthermore, urodynamic evaluation (with the possible addition of video) may assist in identifying DO or ISD.

The options for retreatment of persistent or recurrent SUI are: conservative management (including PFMT with biofeedback), tightening the previous MUS, or repeat anti-incontinence surgery (colposuspension, MUS, autologous PVS, and urethral bulking). In a review of the British Society of Urogynaecology database, Patil et al. (2011) found that a repeat retropubic MUS was the most common surgical reintervention after any failed MUS (54%; 170/313). Bulking, TVT-O, TOT, colposuspensions, and Aldridge slings were performed in 14%, 12%, 8%, 6%, and 2%, respectively. Overall, the data guiding the choice of procedure is woefully inadequate, with a Cochrane systematic review identifying 12 trials, but none meeting eligibility criteria (Bakali et al., 2013). Six of these trials were RCTs but were not eligible because the previous incontinence surgery was not a MUS.

There are essentially no data supporting nonsurgical means for curing post-MUS SUI, and the data regarding sling tightening is limited to case reports. Gaddi et al. (2014) suggested periurethral bulking as salvage therapy after failed sling. In a retrospective analysis of 6914 MUS, 165 women underwent a repeat procedure for recurrent SUI, including 98 MUS and 67 urethral bulking procedures. Eleven of the 98 women who underwent MUS were considered failures (11.2%), and 26 of the 67 women (38.8%) in the urethral bulking group failed ($P = 0.004$). There were no differences in perioperative complications or adverse events between the groups. In multivariable logistic regression, risk for failure was significantly higher in those undergoing urethral bulking compared with those undergoing mid-urethral sling (OR 3.49, 95% CI 1.34 to 9.09, $P = 0.01$).

Repeat MUS is certainly an option for primary MUS failure, and the expected success rates are 62% to 89% (Gaddi et al., 2014). This option is appealing because of its minimal attendant morbidity and overall high success rates, even as a secondary procedure. Risk factors for failure of the secondary MUS are lack of urethral mobility, preoperative ISD, and TO MUS as the secondary procedure. Finally, autologous PVS is an option for recurrent and persistent SUI. The advantage of this surgical option is that it places the sling in a location/vector that is distinctly different from that of the MUS. The downside is that there is a greater chance for postoperative voiding dysfunction and harvest site morbidity. The literature suggests that the use of autologous PVS for primary MUS failure is increasing. Zimmern et al. (2016) noted that, of those women in the TOMUS trial undergoing secondary treatment for primary MUS failure, one-half underwent urethral bulking, and one-half underwent autologous PVS. Other small studies support the upward trend of autologous PVS for this indication (McCoy et al., 2016; Milose et al., 2015; Petrou et al., 2016). The three retrospective studies included 147 women, and subjective cure utilizing different outcome measures was 52% to 76% at follow-up periods of up to 3 years. Objective cure was 91% in the study by McCoy et al. (2016), however 22% of the patients in their cohort required a mean of 1.8 subsequent interventions at an average of 6.5 months after autologous PVS placement. Furthermore, some women in these cohorts had evidence of mesh-related complications and underwent concomitant MUS revision at the time of PVS.

In a recent study, Singla et al. (2017) described their cohort of 99 women who underwent MUS removal for various indications over a 10-year period. Seventy percent and 20% originally underwent retropubic and transobturator MUS, respectively. After subtotal sling excision, 72 (72%) experienced some form of incontinence at a mean of 58 months, with SUI, UUI, and MUI present in 36%, 19%, and 44%, respectively. The success rate after a single minimally invasive intervention for incontinence after sling excision was 81%, 86%, and 75% in women with SUI, UUI, and MUI, respectively.

Regulatory and Legal Issues Related to Sling Mesh Complications

The FDA approved the first MUS for use through the 510(k) approval process in 1998. It is interesting to note that all subsequent MUS products have also been approved for use through this process (Secunda, 2011). The 510(k) approval process for class II products (mesh products fall into this class) allows medical device manufacturers to bypass the normal premarket approval (PMA) procedure as long as the new device is substantially equivalent to an existing product (FDA, 2013a, 2013b). Once the FDA determines that a product is substantially equivalent to an existing product, the company receives a letter of approval to market the new device.

The success of MUS for female urinary incontinence led to the development of transvaginal mesh products for POP repair. Subsequently, the FDA determined that these products were substantially equivalent to existing mesh products already approved, and, in turn, the 510(k) approval process led to the rapid approval of these products as well. The FDA and many physicians believe that the 510(k) approval process is a necessary and important practice that allows for medical device advances to occur more rapidly. Of note, through the Freedom of Information Act (5 U.S.C. § 552(a)(2) (Title 5 United States Code section 552 subsection a2), all FDA letter communications to manufacturers are available online.

However, although the use of transvaginal mesh for POP repairs has increased, so too have complications related to its use. In October 2008, the FDA released a public health notification (PHN) alerting the public about “rare” complications and problems related to transvaginal mesh products used for POP. **In 2011, the FDA modified this alert by removing the term “rare” and stating that surgical mesh for POP repair does not conclusively improve outcomes over traditional nonmesh or native tissue repairs and is associated**

with unique potentially serious adverse outcomes (FDA, 2011).

The FDA convened an advisory panel in September of 2011 to solicit recommendations on potential actions regarding urogynecologic surgical mesh for transvaginal POP repair. If a product approved by the FDA through the 510(k) process is found to have potential serious adverse health consequences, the FDA can require the manufacturer to perform costly 522 postmarket surveillance studies. In the case of mesh for pelvic surgery, the FDA was alerted to potential serious adverse events through the MAUDE database and reports in the urologic and gynecologic literature. In January 2012, the FDA mandated that all manufacturers of synthetic prosthetic mesh and biologic graft materials marketed for POP repair and SIMS perform 522 postmarket surveillance studies. Approximately 100 orders were sent to 35 vaginal mesh manufacturers to conduct such studies.

MUS products (except SIMS) were excluded from this mandate because the FDA advisory panel deemed existing MUS products “safe and effective” and recommended that these products not undergo 522 postmarket surveillance. For future MUS products, the FDA determined that the 510(k) approval process is still applicable as long as well-designed bench or animal studies are included with the 510(k) application. However, premarket clinical studies for new SUI products may be required if the FDA determines that there is a need for clinical information to demonstrate substantial equivalence to an existing product (Baxley, 2011).

The FDA subsequently issued two proposed orders in May 2014: (1) to reclassify the transvaginal surgical mesh for POP repair from class II to class III and reclassify instrumentation for the placement of such mesh products from class I to class II, and (2) require those manufacturers who wish to continue to market these products to submit a PMA application within 30 months of reclassification (January 4, 2016). Without such a PMA, commercial distribution of the device would have to cease, unless the manufacturer obtained an application for an investigational device exemption (IDE). The reclassification and PMA orders did not, and do not currently, apply to full-length retropubic or transobturator MUS.

As a class II device, mesh products or kits were deemed safe without premarket studies, and only required issuance of performance standards, postmarket surveillance, patient registries, guidelines, and recommendations. However, a class III device is one for which insufficient information exists to determine a reasonable assurance of safety and effectiveness, and for which there may be a potential unreasonable risk for illness or injury. (Effective Date of Requirement for PreMarket Approval for Surgical Mesh for Transvaginal Pelvic Organ Prolapse Repair. Federal Register, Vol 79, No. 84; pp 24642-24648, May 1, 2014.; Reclassification of Surgical Mesh for Transvaginal Pelvic Organ Prolapse Repair and Surgical Instrumentation for Urogynecologic Surgical Mesh Procedures: Designations of Special Controls for Urogynecologic Surgical Mesh Instrumentation. Federal Register, Vol 79, No. 84; p 23634–24642, May 1, 2014.)

On January 4, 2016, the FDA issued two final orders to manufacturers and the public regarding the use of surgical mesh for transvaginal POP repair. The FDA issued one order to reclassify these medical devices from class II, which generally includes moderate-risk devices, to class III, which includes high-risk devices. The second order requires manufacturers to submit a PMA application to support the safety and effectiveness of surgical mesh for transvaginal POP repair. The PMA pathway will require manufacturers to address safety concerns, including severe pelvic pain and organ perforation, to demonstrate safety and effectiveness.

These orders do not apply to surgical mesh used for other indications. Full-length MUS and mesh for sacral colpopexy remain class II devices, and SIMS are currently undergoing postmarket surveillance 522 order studies. The PMA requirements for class III devices must now include at least 1 year of outcome data with an additional 2 to 4 years of postmarket follow-up, more robust physician labeling (warnings and precautions), and patient labeling that must include an explanation of POP, treatment options, clinical trial data, a statement that surgical mesh is permanent, instructions for postoperative care, and a notice of availability of the FDA Safety Communication. All existing transvaginal mesh POP products will be required to complete the 522 order studies. The 510(k) process will no longer be used for new products, as all new products will be deemed class III and must undergo the PMA process.

Even though the FDA has determined that existing MUS products are safe and effective, this unfortunately has not prevented MUS from being caught up in the fervor of litigation related to products used for pelvic organ prolapse repair. In June 2010, a settlement was reached to halt the first class-action lawsuit against the manufacturer of ObTape (Mentor-Porgés) (Chapple et al., 2013). To date, AMS (Endo Pharmaceuticals), Ethicon (Gynecare, Johnson & Johnson), Boston Scientific, and C.R. Bard have all been targeted by multidistrict federal litigation for complications related to their MUS products.

The increase in litigation has been accompanied by MUS products being removed from the market. In June 2012, Ethicon withdrew four products, including TVT-S, stating that the move “was not a recall, but was based on the products’ commercial viability in light of changing market dynamics, and is not related to safety or efficacy.” Ethicon asked the FDA for permission to discontinue sales of the devices and to suspend requirements for additional studies on its Gynecare line of products. No official recall of devices was formally issued by the FDA since manufacturers voluntarily withdrew certain mesh products that they did not want to enroll into postmarket surveillance studies. Bard Medical Division discontinued the distribution and sale of the Align and Align TO MUS products in the United States as of June 1, 2016, and Endo International/Astora (SPARC and Monarc) discontinued commercial and manufacturing operations by March 31, 2016. Currently, most litigation is directed at device manufacturers; however, this could change.

It is important for pelvic surgeons to continue to thoroughly counsel their patients about the permanent nature of mesh products and the potentially serious complications related to their use. The AUA has come out with a position statement supporting the safety and efficacy of polypropylene MUS (AUA Position Statement on the Use of Vaginal Mesh for the Surgical Treatment of Stress Urinary Incontinence [SUI]).

Extensive data exist to support the use of synthetic polypropylene mesh suburethral slings for the treatment of female SUI, with minimal morbidity compared with alternative surgeries. Advantages include shorter operative time/anesthetic need, reduced surgical pain, reduced hospitalization, and reduced voiding dysfunction. Mesh-related complications can occur after polypropylene sling placement, but the rate of these complications is acceptably low. Furthermore, it is important to recognize that many sling-related complications are not unique to mesh surgeries and are known to occur with nonmesh sling procedures as well. It is the AUA's opinion that any restriction of the use of synthetic polypropylene mesh suburethral slings would be a disservice to women who choose surgical correction of SUI. Additionally, **both the Society of Urodynamics, Female Pelvic Medicine and Urogenital Reconstruction (SUFU) and the AUA support the use of multi-incision monofilament mid-urethral slings for the treatment of SUI in properly selected patients who are appropriately counseled regarding this surgical procedure by surgeons who are trained in the placement of such devices, and the recognition and management of potential complications associated with their use.**

Multiple case series and randomized controlled trials attest to the efficacy of synthetic polypropylene mesh slings at 5 to 10 years. This efficacy is equivalent or superior to other surgical techniques. There is no significant increase in adverse events observed over this period of follow-up. Based on these data, the AUA guideline for the Surgical Management of Stress Urinary Incontinence concluded that synthetic slings are an appropriate treatment choice for women with stress incontinence, with similar efficacy but less morbidity than conventional nonmesh sling techniques (Appell et al., 2009). The AUA guideline also indicates that intra-operative cystoscopy should be performed during all synthetic sling procedures to identify urinary tract injury. The most recent AUA/SUFU SUI guidelines have echoed these statements (Kobashi et al., 2017).

The AUA strongly agrees with the FDA that a thorough informed consent should be conducted before synthetic sling surgery. The AUA also agrees that surgeons who wish to perform synthetic sling surgery should:

- Undergo rigorous training in the principles of pelvic anatomy and pelvic surgery.
- Be properly trained in specific sling techniques.
- Be able to recognize and manage complications associated with synthetic mesh sling placement.

Finally, as carcinogenic potential must be considered for any surgical implant, several authors have addressed this topic. Of 2361 MUS procedures performed at the Cleveland Clinic over a 10-year period, bladder cancer was diagnosed in one woman (0.04%) (King et al., 2014). Likewise, Linder et al. (2016) diagnosed only two pelvic cancers (vaginal melanoma 3 years after MUS and an ovarian tumor 1 year after MUS) in a 10-year experience of 2474 women from the Mayo Clinic. Reviews of the literature confirm the absence of association between polypropylene mesh and carcinogenesis (Adel et al., 2017; King and Goldman, 2014).

Videos 125.1 to 125.5 show procedures related to this chapter.
